points H and J, with a pendulum KL with heavy bob L to act as driver, and a number of light graduated responders lettered C to C′. The latter have small paper cones about 2 cm. high as bobs, with the addition of split rings of copper wire resting on them to prevent the damping being too great. The driving pendulum has a "tightener" at M to adjust its length, which must be reckoned from L up to N, since when the heavy bob L swings the bridle HKJ swings about the line HNJ. The lengths of the light responders, on the other hand, must be reckoned only up to their suspension point on the cord HK. These light responders have suspensions of thread which are passed through the cord HK and may then be cut off and the adjustment to place made so that the line of the bobs CD—C′ passes through H. This is essential in order that each responder receives an equal inclination by a given displacement of the heavy bob L. In the

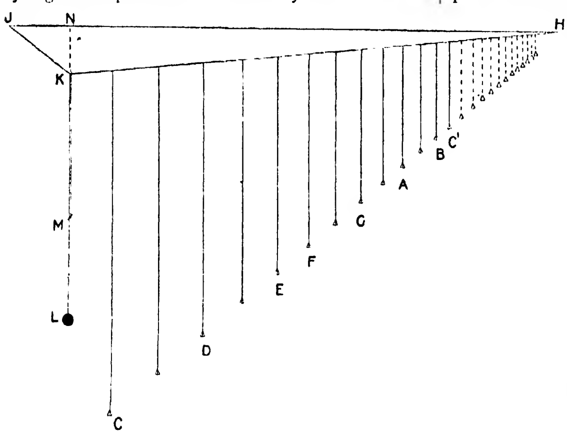

FIG. 1

diagram just one octave of responders is shown, the number being thirteen and the lengths such as to make their relative frequencies those of the consecutive notes on the piano or organ. This allows a fineness of discrimination of pitch in agreement with experience. Of course to represent the whole set of aural mechanisms, seven or more octaves would be needed, but a single octave on the model enables one to carry out a number of interesting tests, though for some, two octaves are necessary, as shown by dotted lines in the figure. For the latter the lengths of the responders (and also the distances from H of their points of suspension) may be as follows: 57·05, 50·8, 45·25, 40·3, 35·9, 32·0, 28·5, 25·4, 22·6, 20·16, 18·0, 16·0, 14·25, 12·7, 11·3, 10·1, 9·0, 8·0, 7·13, 6·35, 5·65, 5·04, 4·49, 4·0, 3·55 cm. Any consecutive thirteen values will do for a single octave.

We may now test the behaviour of such a model and ascertain if in essential features it typifies the mechanism in the ear, although of course it is not for a moment imagined that any pendulums exist in the ear. If vibratory responders exist there they must be of an elastic nature.

If the seven octaves or more of responders were provided we should have the musical range of seven octaves accounted for. Further, the lack of precise discrimination of pitch for very high notes and for very low notes is explained also. Thus, for any note well within the range of the responders, when the pendulum bob L is swung, thus representing by its frequency a certain note, the responders vibrate in response, the one best in tune vibrating most, the others near it, *both above and below*, showing a rather less response. Hence the pitch is recognised and located by this behaviour. But if the pendulum LN is made shorter than the shortest or longer than the longest responder provided, then we have the responders near the end in question responding best but no maximum response with a *return to quiescence beyond it*. Thus the exact pitch cannot be located, and this agrees with experience. Consider next the discrimination of pitch between notes very near in pitch, and let us ascertain what is possible when the adjacent responders differ in pitch by a semitone or one-twelfth of an octave. It will be easily ascertained that a discrimination of pitch of about the twentieth of this semitone is possible. For by adjusting the tightener M on the suspension KL, we can make the response of two adjacent pendulums equal, and then by repeatedly lengthening the heavy or driving pendulum the response of the lower of the two light pendulums may be increased and that of the higher one decreased till the lower one just shows a maximum, the adjacent ones above and below being alike in their response. We should then have passed over the half of a semitone only and ten steps are susceptible of discrimination in this range. Without any wire rings on the paper cones the responders would not succeed in this test, but with the rings to weight the cones there is less damping, sharper resonance, and adequate discrimination.

If two octaves of responders are provided very striking experiments can be shown as to the recognition of the overtones essential to notes of a certain quality of tone. Thus, setting the pendulum NL to the pitch of a low responder, say the third from the bottom, if the pendulum swings freely we have a responsive maximum at that responder. But if the bob L is grasped in the hand and swung to and fro in the same period as before, but with a "dimple" at one end of the swing, it is really executing tone and octave, and the responders will promptly show the corresponding two resonance humps. Again, if the bob L is swung to and fro, with a "dimple" at each end, it is really executing tone and twelfth (frequencies 1 and 3), and the responders give the corresponding two resonances. Lastly, if the bob L is moved smoothly from end to end in one direction, but returns with two kinks or dimples, we have really a vibration consisting of tone, octave and twelfth (frequencies as 1, 2 and 3), and the three appropriate resonance humps are shown by the set of responders.

Thus, without overstraining or even exhausting the

possibilities of the resonance theory it seems easy by its use to account for the main facts of audition, none of which seem in conflict with the theory. This, of course, does not suffice to establish the hypothesis, as it is conceivable that some other might be equally successful. But, pending the advent of such a rival, perhaps the disciples of Helmholtz may be pardoned for what others might style their inexplicable interest in an old and unproved theory.

The Lesser Whitethroat's Fanfare.

(To J. S. H.)

THOUGH lyrics mingled with tattoos
Of melodrama savour,
The Lesser Whitethroat dares to use
Both avenues to favour.
Behind a screen
Of leaves unseen
He'll croon with tenderest passion,
Then loudly reel
A clarion peal
Of notes in fanfare fashion :
(*Sotto voce, pp*) *Chi'ddy-choo-ee'cheo,-Wee'jo-choo-ee'chey,*
Wee'-chiddy-wee'chey,-Choo-i'ddy, Choo-ee' !
Then changing time,
And reckless of rhyme :
(*Vivace, ff.*) JIP-JIP-JIP-JIP,
JIP-JIP-JIP-JIP,
JIP-JIP !

But can we give this Warbler praise
When art he compromises,—
In secret hums his native lays,
And flash-notes advertises ?
Sing, Warbler, sing !
These cries you fling
Too soon all tune will smother ;
And then you'll flit
A ribald Tit,
And Whitethroats lose their brother !

W. GARSTANG.

Obituary.

W. H. HUDSON.

THE death of Mr. William Henry Hudson at his residence in London on August 18, in his eighty-first year, removes from our midst a remarkable personality, a great writer of English prose, and a keen interpreter of Nature.

Mr. Hudson's father emigrated to the Argentine in the early part of the last century and settled on the pampas, and it was there that his childhood and early life was spent. We get a vivid idea of the conditions under which he grew to manhood in the pages of "Far Away and Long Ago," a volume of autobiographical recollections which he published in 1918—the vast treeless plains, the solitary estancia with a few trees around it, the semi-savage gauchos, and above all the teeming bird life along the strand of a lonely mere.

In his early days Mr. Hudson entered into correspondence with the late Dr. P. L. Sclater and sent him collections of birds and mammals. Accounts of these, first appearing in the Proceedings of the Zoological Society, formed the foundation of a joint work, "Argentine Ornithology," published in two volumes in 1888-1889, to which Mr. Hudson contributed the notes and observations on the habits of the birds, while Dr. Sclater was responsible for the technical descriptions and general arrangement. This work was recently reissued by Mr. Hudson alone, but without the technical descriptions, under the title of "Birds of La Plata." Two other volumes, well known to lovers of good writing dealing with South American Natural History, were "The Naturalist in La Plata," 1892, and "Idle Days in Patagonia," 1893.

About this time Mr. Hudson came to England and began a long series of works dealing with the study of Nature in England. "Birds of a Village," "Nature in Downland," "Hampshire Days," "The Land's End," and the more strictly ornithological "British Birds," "Birds and Man," and "Birds in London," followed one another in quick succession. Though always in feeble health and of a delicate constitution, he tramped over southern England from the New Forest to Penzance throughout the summer, spending the winter partly in London and partly at Penzance, where he made his second home.

Recognition of his talent came late to him. In his early days in England he was unable to earn a livelihood with his pen and he was awarded in 1901 a Civil List Pension of 150*l.* in "recognition of the originality of his writings on natural history." This he resigned in August last year on the ground that he needed it no longer. "Publishers," he told an intimate friend, "threw money at him with both hands."

A man of extremely sensitive temperament, Hudson could not endure to take the life of any animal or bird, and was an ardent supporter of the Society for the Protection of Birds, to which he devoted much of his energy during recent years. He was thus out of sympathy with any form of collecting. He had, however, a wonderful power of observation, and his sense of hearing was extremely acute. His writing is simple, lucid, and descriptive, and he never gave to his observations on bird or animal psychology that anthropomorphic tendency which so often characterises the writers of popular works on natural history subjects. Though he can never be reckoned among the ranks of scientific ornithologists, his writings will undoubtedly endure as monuments of accurate observation and of limpid, lucid, English prose.

Current Topics and Events.

IN an address to the Rothamsted branch of the National Union of Scientific Workers, reported in the *Scientific Worker* for June, Prof. A. L Bowley pleaded, as so many have done, for an "interpreter" to mediate between science and the laity. He suggests that "one test of greatness in works of art is that they should make a direct appeal to those whose powers of appreciation are not specialised," and, by analogy, that the greatest science should be the most easily interpreted. But what does the analogy really prove? The "art" which is appreciated without *any* specialisation is that of the Merry Widow waltz or Poems of Cheer; the appreciation of a Bach fugue or a Shakespeare sonnet *does* require some "specialisation"; it requires, not practice of the art, but some deliberate self-education. If the laity would (or could) educate themselves in science as they do in art, interpreters might be forthcoming who would do for science what in our generation Berenson and Mr Roger Fry have done for painting or Sir Henry Wood and Mr Ernest Newman for music. The difficulty now is that the wholly "unspecialised" laity demand "interpretation" in terms of concepts of which science denies the validity, just as they demand sensual prettiness in painting and catchiness of tune in music. Before interpretation can begin there must be an effort to understand, men of Prof. Bowley's eminence in other branches of learning must not pronounce *ex cathedra* that "science is not beautiful"; men must know that science is beautiful —to those who will train themselves to appreciate its beauty.

THE *Museums Journal* for July 1922 criticises the announcement of the Board of Education that in future local authorities will be charged with half the actual cost of transporting the collections sent on loan from the Victoria and Albert Museum to provincial museums and art galleries Hitherto there has been a uniform charge of *2l.* 10*s.* The change will make little difference to places near London, but will be prohibitive for the less wealthy distant towns. The collections of the Victoria and Albert Museum were originally intended to help museums and students throughout the country. Gradually there arose a division between the objects retained in the museum and those put into circulation; but the Circulation Department remained an important section of the museum. Now it is contended that the two are "in hopeless competition in regard to purchase of objects." This, if true, is absurd, and we agree that something should be done to co-ordinate the work of the various national museums *inter se* and with the work of the provincial museums.

WHILE the *Museums Journal* seems to be of the opinion that the national museums do not do enough for those in the provinces, Mr. Lawrence Haward, in a lecture to the Royal Society of Arts (published in the Journal of the Royal Society of Arts for July 28, and in the *Museums Journal* for July and August 1922), says: "If more has not been done to make the National Collections available to the nation, as distinct from the inhabitants of London, it is largely, I think, because the provincial galleries have not always realised how ungrudgingly those in authority in the great National Galleries and Museums will impart their knowledge and render assistance in a variety of ways to their provincial colleagues out of the abundance of their own treasures." And again, he says of provincial museums: "If only they know how to use their opportunities, and are given a fair chance of putting their knowledge into practice, they can become a really vital influence in the town . . . acting as cultural centres for the whole community." Without attempting to decide whether it is the national museums or the provincial museums that are most to blame, such acquaintance as we have with the work of both has forced us to the conclusion that the provincial public does not sufficiently appreciate the advantages of its own local museums, and frequently worries the officials of metropolitan institutions with questions that would have been much more conveniently dealt with nearer home.

IN commemoration of the bi-centenary of the appointment of Bernard de Jussieu as demonstrator of botany at the Paris Jardin des Plantes, the Abbé L. Parcot in *La Nature* (July 1) gives an interesting account of his work, especially the foundation of the Botanic Garden at the Petit Trianon at Versailles The latter was of supreme interest as the birth-place of the natural system of classification of plants De Jussieu was commissioned in 1750 by Louis XV. to lay out a botanic garden at Petit Trianon Sixteen years before, Linnaeus had published his artificial system of classification which was enthusiastically adopted by botanists owing to its simplicity of working, as it was based on obvious characters of the sexual organs. Linnaeus had, however, also published some "Fragmenta" of a natural system; that is, one in which plants were arranged according to the sum of relationships of all their characters Starting with these "Fragmenta," de Jussieu developed a system according to which he arranged the plants in his new garden, and prepared a manuscript catalogue indicating the grouping of the genera in families, and also the list of species included under the genera. This catalogue was published by his nephew, Antoine Laurent de Jussieu, in 1789, twelve years after the death of Jussieu himself The system was further elaborated by Antoine, and later by Augustin Pyrame de Candolle, and attained its modern development in the classic work of Bentham and Hooker. The famous botanical school and garden of the Trianon were dispersed after the death of Louis XV, and for a long time the site of the garden was uncertain. L'Abbé Parcot has, however, reproduced in *La Nature* some original plans in which the position of the garden is indicated, to the right of the chateau. a cedar of Lebanon and other conifers remain where they were planted by de Jussieu, and a few other of his trees which were replanted in the lawns and flower garden are still standing.

An imposing scientific expedition set out from San Diego on July 9 last for a two months' cruise among the islands off the west coast of Lower California. According to *Science*, the chief object of the expedition is to make investigations into the present abundance and condition of the southern fur seal, the southern sea otter, and the elephant seal in the localities visited. It had been thought that these valuable animals were extinct, but recent discoveries have shown that a few still exist, and combined action of the United States and the Mexican Governments is necessary for their preservation and exploitation. Advantage will be taken of the opportunity for making surveys of the flora, fauna, and geology of the islands, which hitherto have been but little explored. The expedition has been under consideration by the California Academy of Sciences for some time past, and its realisation has been made possible by the co-operation of the Government of Mexico and a number of American institutions, including the San Diego Museum of Natural History, the Scripps Institution for Biological Research, the National Geographic Society, and the Pacific Division of the American Association for the Advancement of Science. The Mexican Government has loaned the fishery guard boat *Tecate* for the expedition and has accepted as its guests all members of the expedition sent by American institutions. Sen Carlos Cuesta Terron, professor of herpetology and biology in the National Museum of Natural History of Mexico and a Government representative on the expedition, is director, but the scientific investigations will be in the immediate charge of Dr G Dallas Hanna, of the California Academy of Sciences, and A W. Anthony, of the San Diego Museum of Natural History

Mr Ernest A Smith has resigned his position as secretary of the British Non-Ferrous Metals Research Association and accepted an appointment as research metallurgist to the Sheffield Smelting Company, Ltd

Mrs Kapp writes to correct a statement respecting her late husband's parentage that appeared in the obituary notice in Nature of August 19 She informs us that Prof Gisbert Kapp's father was not German but a native of Trieste and the governing civil councillor of that city

Engineer Vice-Admiral Sir George Goodwin, late Engineer-in-Chief of the Fleet, and Dr James Colquhoun Irvine, vice-chancellor and principal of the University of St. Andrews, have been appointed members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

The *Times* of August 28 announces that a special Press telegram from Prof J W Gregory, of Glasgow University, reports his safe arrival at Talifu, Yunnan, after a successful journey in Tibet It will be remembered that Prof Gregory and his son, Mr C J Gregory, left England for Rangoon at the end of March last with the object of investigating some features in the mountain structure of north-western Yunnan and western Szechuan (see Nature, January 12, 1922, vol. 109, p 51).

A novel feature of the forthcoming Swansea meeting of the Institute of Metals will be the inauguration of a series of annual public lectures on subjects of practical interest to those engaged in the non-ferrous metals industry Dr R S Hutton, director of the British Non-Ferrous Metals Research Association, is to deliver the first, which will be entitled "The Science of Human Effort (Motion Study and Vocational Training)," on September 19 Further particulars of the meeting, which will be held on September 19-22, can be obtained from the Secretary, Mr G Shaw Scott, 36 Victoria Street, London, S W 1

A note on *The Pan-American Geologist*, published in Nature on July 1, has brought from the office of *Economic Geology* a letter (unsigned) stating that *The American Geologist* still remains incorporated with that journal, and that the names of some geologists given as associate editors of *The Pan-American Geologist* were used without permission If we have repeated erroneous statements we regret it, but those statements had been in our hands for some months, and were not published by us until we saw actual parts of *The Pan-American Geologist*, which appeared to confirm them

The Cleveland Technical Institute at Middlesbrough has issued for nearly a year a monthly Bulletin containing abstracts of the most important scientific and technical articles which have appeared in home and foreign periodicals during the month The Bulletin is printed on one side of the page only, and each issue consists of about 60 pages Each abstract is on the average about half a page in length, and the intention is that those of interest to the reader shall be cut out by him, pasted on cards, and placed in their proper position in a card catalogue They are classified under the headings chemistry and physics of iron and steel, mechanical and electrical engineering, fuel and fuel technology, shipbuilding and marine engineering, foundry practice, non-ferrous alloys, industrial chemistry, blast furnace practice, and steel-making A few pages are devoted occasionally to short accounts of recent home and foreign patents, and a list of recent technical publications is generally given each month As a means of keeping those engaged in industry well up to date the Bulletin deserves every support

Among the autumn announcements of Messrs. Chapman and Hall, Ltd, we notice the following. "Practical Applications of X rays," by Dr G. W C Kaye, in which will be described the various uses to which the rays can be put in commerce, and Vol 2 of "Mechanical Testing," by R G Batson and J H Hyde, entitled "Testing of Apparatus, Machines, and Structures" The work will deal with the methods of testing Dynamometers, Gear Boxes, Girders, Reinforced Concrete Structures, Pumps, Springs, Ball-bearings, etc. In the "Directly-useful Technical Series," "Electrical Measuring Instruments and Supply Meters," by D. J. Bolton, will be issued.

Research Items.

CHILD SACRIFICE AT CARTHAGE.—Historical evidence goes to show that the sacrifice of children to the Mother Goddess was not infrequent. Two French archaeologists, M. Poinssote and M. Lautier, engaged in exploring the ruins of ancient Carthage, have unearthed in front of an altar near a temple of Tanit three vaults containing the charred bones of new-born babies and children from two to three years of age. The archaeologists believe that to the left of the altar was a stone slab with a bronze grill, under which burnt a fierce fire, and here the naked bodies of the first-born were offered in accordance with the ancient rites which were regularly practised from the sixth or seventh centuries before the Christian era until the destruction of Carthage by the Romans. Others, however, believe that it was customary for the parents to reclaim the remains of sacrificed children, and that the bones now found, a gruesome pile 15 feet high, are the remains of sacrificed children placed by their parents under the protection of the all-powerful Tanit.

A POLYNESIAN MUSEUM.—The Bernice Pauahi Bishop Museum at Honolulu, Hawaii, was founded in 1889, by her husband, Charles Reed Bishop, as a memorial of Princess Pauahi, the last of the Kamehameha family of the chiefs of Hawaii. It is devoted to the study of Polynesian and kindred antiquities, ethnology, and natural history. Besides the material from Polynesia and other Pacific islands, that from Hawaii is the largest and most important. A large staff of experts is employed in research and the collection of specimens, which are of large and increasing value. The Museum has recently published a useful collection of proverbial sayings of the Tongans, compiled by Messrs. E. E. V. Collocott and J. Havea, which, in addition to its value to students of proverbs and linguists, contains a number of useful notes on the folk-lore and customs of the people.

HEAD-HUNTING IN ASSAM.—Mr. L. H. Hutton, the author of two important works on the Angami and Sema Nagas, contributes a paper to the August issue of *Man* on the method in which the heads of victims are decorated and divided. In addition to complete skulls adorned with mithan or buffalo horns, or with wooden imitations of these, many houses had trophies hung up in which the skull was only partly human, the taker having got only a share of the head. In such cases the rest of the head is made of wood, or the skull of an animal, such as a pig, while in another the missing half was ingeniously fabricated from two skulls of the black gibbon (*Hylobates hylok*), making the skull look as if it had three eyes. The object of the horns is said to be to prevent the dead man hearing the call of his friends searching for him, as, if his soul were to go to them, it would instigate them to revenge, whereas if it remain with the taker of the head, it lures its late relations to put themselves within reach of the possessor of the head, and lose their own to him as well. Some Ao villages used to attain the same end by stringing the skull of one of their own dogs above the skull of their enemy. The soul of the dog made such a barking whenever the strange relations of the dead man came within call of him that he never heard them imploring his soul to return.

HUMPBACK WHALE FROM THE MIOCENE OF CALIFORNIA.—How often does it happen that what proves to be a valuable fossil becomes irretrievably damaged before its importance is recognised. This appears to have been the case with a specimen of Megaptera from the Miocene Diatomaceous earth of Lompoc, California. The remaining incomplete skull has been studied by R. Kellogg (Proc. U.S. Nat. Mus., vol. lxi., art. 14), who points out that the discovery of this Miocene member of the Mystacoceti gives additional force to the views of those who have advocated the great antiquity of the Cetacea, for so highly specialised a form occurring in strata of this age affords further evidence for assuming that the evolution of the Cetacea has taken a longer period than heretofore considered plausible. A careful detailed description, illustrated by plates and text figures, completes this paper on *Megaptera miocæna*, n. sp.

PHYLOGENY OF OCHETOCERAS.—The Ammonite genus Ochetoceras, belonging to the family Harpoceratidæ, is confined to the Lusitanian, Kimmeridgian, and Portlandian divisions of the Upper Jurassic and was derived from the Middle Jurassic Oppelia. The numerous species, according to Marjorie O'Connell (Bull. Amer. Mus. Nat. Hist., vol. xlvi.), are found to fall into three phyletic series: those of (1) *Ochetoceras arolicum*, (2) *O. hispidum*, and (3) *O. canaliculatum*. The relations of the European species of the first series and the Mexican and Cuban of the other two are here set forth for the first time. These relationships are shown in a series of tables and the various species discussed and described. In all three series the same orthogenetic trends in development are traceable and consist in: (*a*) A progressive diminution in the ratio of width to height of whorl and width of whorl to diameter; (*b*) a progressive diminution in the coarseness of the costæ, (*c*) the branching of the primary costæ at their ventral ends, and finally, (*d*), the branching of the intercalated costæ, or striæ.

EOCENE MOLLUSCA AND FORAMINIFERA FROM NIGERIA.—For some years past scattered information has been obtained concerning the Tertiary fossils of Nigeria, and some of the Vertebrata have been described, but there yet existed a considerable amount of unpublished material. This through the auspices of the Geological Survey of Nigeria (established in 1919) is now being collected for publication, and the Survey's third Bulletin is devoted to the Eocene Mollusca, described by R. Bullen Newton, with an appendix on the Foraminifera by E. Heron-Allen and A. Earland. It is no slight on the eminent authors of the Appendix to say that it is necessarily mainly a list of species, since the sample submitted to them was small. It is of interest, however, to note the almost complete absence of the characteristic Eocene genus Nummulites. The bulk of the paper is devoted to the description of the Mollusca, and great credit is due to Mr. Bullen Newton for the excellent way in which this is done. In all, seventy-three species are described and of these more than half are definitely new and worthy of better illustration than seemingly could be given them. The results of Mr. Newton's study of these Nigerian Mollusca are exceedingly interesting, for he is able to show that the fauna is of Middle Eocene or Lutetian origin, and that some of the forms are closely allied to, if not identical with, British examples from the same geological horizon, that others agree with species occurring in the Upper Mokattam Beds of Egypt; while yet others have affinities with fossils from the Middle Eocenes of Alabama. Among these last is a representative of the genus Bulbifusus, hitherto known only from America. Truly a strange linking together in past ages of remote parts of the

globe, still more emphasised by the recent discovery of one of the species, *Cardita* [= *Venericadia*] *planicosta*, in Peru (NATURE, April 29, 1922, p. 561).

THE ORIGIN OF IGNEOUS ROCKS RICH IN ALKALIES.—Dr. S. J. Shand ("The Nepheline Rocks of Sekukuniland," Trans Geol Soc., S Africa, vol. xxiv. p. 111, 1921), discusses an occurrence of the so-called alkaline igneous rocks in and around the farm Spitzkop in the Transvaal Following the work of N. L. Bowen, he holds that the original magma separated during cooling into a norite and a mass rich in alkalies The latter rose towards the surface through the well-known dolomite formation, and floated up a huge mass of limestone, which has a visible area of half a square mile By reaction with the limestone, as R A Daly has urged in other cases, a nepheline-syenite (foyaite) magma was produced, which becomes much more calcareous in the neighbourhood of the limestone The author furnishes a good review of the whole question in "The Problem of the Alkaline Rocks" (Proc Geol. Soc, S Africa, 1922, p xix). He defines an alkaline rock by pointing out that in common igneous rocks the alkali-metals [does he not mean their oxides ?] "are combined with alumina and silica in the molecular proportion of 1 . 1 . 6 (in felspars) or 1 . 3 . 6 (in micas) An alkaline rock, if names are to mean anything, should be one in which the alkalies are in excess of the 1 . 1 . 6 ratio, either alumina or silica or both being deficient" He then discusses the work of N L Bowen, who, since the publication of Shand's paper, and in association with G. W. Morey, has shown that orthoclase, at about 1200°, does not melt as a whole, but yields leucite and a glass (Am Journ Sci, vol cciv. p 1, 1922) Bowen and Morey point out that leucite may thus arise as a temporary mineral in cooling granite magmas, since it breaks up into orthoclase and nepheline, the characteristic minerals of the nepheline-syenites may arise in association through this intermediate phase

BIRDS MARKED IN EUROPE RECOVERED IN SOUTH AFRICA —In the August number of *British Birds* Mr. H F Witherby records the recovery at Jansenville, Cape Province, on January 8, 1922, of a swallow ringed as a nestling in Berkshire on August 20, 1921 Details of the five previous records of the kind are recapitulated, with a useful map, but these have already been quoted in NATURE in Dr Thomson's recent article (March 16, vol 109, p. 346) on the migrations of British swallows In the same publication Mr W L. Sclater directs attention to a record of a common tern marked in East Prussia and recovered in Natal, another common tern marked in Sweden has been recovered in Cape Province, while there is also a remarkable record of one marked in Maine, U S A, and recovered in West Africa Apart from these six swallows and two terns, the only birds which appear to have been recorded by the marking method as travelling from Europe to South Africa are white storks; there are many such records of this species, which has been largely marked in Hungary, Germany, and Denmark, and there are also several very valuable records from intermediate localities such as Central Africa The records of European marked birds recovered in Northern Africa are less restricted as to species and include cases of the lapwing, lesser black-backed gull, starling, swallow, and white stork.

ATTACK ON A MOTH BY A WASP—Miss M M Buchanan sends us from Penrith a specimen of a moth which was caught while fluttering near the ground with a wasp attached to its thorax. The wasp escaped, but one from a nest a couple of yards away was *Vespa vulgaris*, Linn., and the moth was a small Emerald moth (*Geometra vernaria*, Hübn). Wasps, which, as is well known, are almost omnivorous, are in the habit of seizing and carrying off other insects as food for their larvæ, but their chief victims belong to the order Diptera (two-winged flies). Major E. E Austen, of the Natural History Museum, informs us that he has personally witnessed an attack by a wasp on a Drone-Fly (*Eristalis tenax*, Linn.). In this case, in spite of the fact that the victim was the bulkier insect of the two, the wasp flew away with the body of the fly in a very few moments, after first ruthlessly cutting off by means of its powerful mandibles the right wing, the head, and lastly the left wing, all of which from the wasp's point of view were evidently useless encumbrances Since wasps are diurnal in habit, and moths, speaking generally, are the reverse, attacks by the former upon the latter can scarcely be of common occurrence, and the incident described by Miss Buchanan, if not unique, is certainly unusual

NIGERIAN PLANTS OF ECONOMIC VALUE —Part IV. of "The Useful Plants of Nigeria," published as Additional Series IX of the Kew Bulletin, completes the work begun in 1908 by Mr J. H. Holland in collating the information of plants of economic importance in Upper Guinea The remainder of the dicotyledons and the monocotyledons are considered, and a brief note is given on the ferns and fungi Bound with this part is an appendix containing a list of books of general interest on West Africa, a complete index to all four parts, an introduction, and a preface Sir David Prain, in the introduction, states briefly the reasons which led to the work being undertaken and the selection of Mr Holland, from his experience of Nigeria, as compiler In the preface, Mr Holland outlines the arrangement and scope of the work. Among the natural families reviewed in this part, the Euphorbiaceæ and Moraceæ provide many plants of economic importance Under the monocotyledons, valuable information is brought together concerning, among others, the banana, pineapple, sisal hemp, yams, cocoyams, piassava, oil palm, and coconuts The pages on the Gramineæ and the information on fodder grasses are particularly welcome at a time when stock-raising is receiving so much consideration on the Coast The list of references to special works and monographs given at the end of each species will be found very useful, but in the illustrations cited, reference to a typical example, easily accessible, would have saved much space and rendered the work more handy The increased price of this last part raises the cost of the whole work to 1*l*. 8*s*., and may prevent it becoming as popular as it should be Mr Holland is to be congratulated on bringing this compilation to so successful a conclusion. It has entailed many years of careful research, and it fills an important gap in our reference books on West Africa

TIDAL INVESTIGATIONS —The third annual report of the Tidal Institute of the University of Liverpool recounts briefly a number of tidal investigations which have been begun there, but not completed, during the past year The first two years' work established the existence of important residual fluctuations of sea-level, both periodic and irregular, which remain after all those harmonics directly accountable for by the astronomical forces have been removed. Two hypotheses which give some promise of explaining the periodic part of these residuals have been examined, but it is intended to apply further tests before publishing an account of the work. The main investigations of the year relate, however, to the irregular variations of sea-level due to meteorological causes. The method of intensive tidal analysis

adopted at the Institute isolates the unexplained residuals with considerable accuracy, and has already facilitated their reduction to law. The residuals for Newlyn thus obtained, over a period of two months, were shown by Mr. Jolly, of the Ordnance Survey, to be correlated with the local barometric pressure and its gradients in two directions at 7 A.M. on the same day. This work has been modified and extended by Dr. Doodson, who has obtained numerical formulæ, depending on meteorological data, which give corrections for the predicted heights of high and low water at the Port of Liverpool, and there is a prospect of obtaining such corrections on the previous day by forecasting the pressure distribution a day ahead. The report closes with the encouraging statement that a thorough understanding of the effects of meteorological changes is now only a matter of continued effort.

ATLANTIC HURRICANES.—After a period of relative quietness, Atlantic hurricanes are, with the approach of autumn, likely to become a source of danger to vessels traversing the ocean. By the aid of wireless the navigator of the present day has an immense advantage over those of quite recent times, and reports from other vessels as well as from seaports on both sides of the Atlantic can now be received when at sea and charted. The *Monthly Meteorological Chart of the North Atlantic* for September, in addition to its usual information of interest to the sailor, deals with two Atlantic hurricanes experienced in September 1921. The tracks of these hurricanes appeared in the *U.S. Monthly Weather Review*, December 1921, and charts for several days which embraced the storms, as well as descriptive matter, are given in the *Monthly Weather Review*, September 1921. Detailed experiences and observations in the Meteorological Office chart will enable the seaman to see precisely how, when afloat, wireless weather reports may help him. With all the aid he may get, it does not relieve the commander from forming and using his own conclusions, and a knowledge of meteorology is more than ever of use to him. The back of the September chart gives small weather charts for each morning, showing the weather conditions over a large part of the North Atlantic from September 7 to 16. Practically during the whole of this period there were two cyclones travelling first to the north-westward and recurving later to the north-eastward, and some vessels clearly experienced both storms. A study of the various details will facilitate action being taken when in the neighbourhood of similar storms.

MONSOONS AS RAIN MAKERS.—In the *U.S. Geographical Review*, vol. xii., July 1922, is an article by Prof. A. McAdie on monsoon and trade winds as rain makers and desert makers. Naturally there is a large amount of originality in the article, but Prof. McAdie makes it clear that much has been taken from Dr. G. C. Simpson's lecture to the Royal Meteorological Society in March last year. The monsoon is essentially a seasonal wind, and the word is used in this sense all the world over, but those like Dr. Simpson, who with respect to India discuss it from an Indian standpoint, associate the wind with the rainy season from June to September. Prof. McAdie is more especially concerned with the monsoonal influence on the Californian coast, where the seasonal winds in the summer fail to produce rain. The heavy fogs along the Californian coast show that the water vapour is present and yet there is no rain, although the air stream must rise at least 2000 metres, because it is flowing into a region of much higher temperature and the mountains fail to become rain makers. In a midwinter month in California the mountains often rob the air stream of much of the moisture. Instances are given of two consecutive midwinter months showing very different precipitation results. The author states that if the winds can bring rain they can also prevent rain from falling, and can in some cases cause deserts. Although warm moist air may be rising, a strong upper-air current may blow the clouds away and interrupt the process of rain making. At the coming meeting of the British Association at Hull a discussion on monsoons is to be opened by Dr. G. C. Simpson, and some further contributions to the subject may be expected.

SURVEYING INSTRUMENTS.—Messrs. T. Cooke and Sons, Ltd., Buckingham Works, York, have issued a revised Price List of the instruments in their Catalogue No. 256, which includes all the surveying apparatus and instruments in ordinary use among engineers and surveyors. Certain of the less common types of instruments in previous lists have disappeared, and component parts of existing types have been standardised so far as possible to cut down production costs. A great variety of well-designed theodolites are described and illustrated, ranging from the simple type of builder's transit to the "geodetic" and the "universal" micrometer instruments, giving direct readings to single seconds of arc. A full range of surveyors' levels is also listed, including the U.S. Coast and Geodetic Survey pattern, which has been specially designed for precision work and affords an exceptionally high degree of accuracy. Details are given of the various types and sizes of spirit bubbles which are manufactured by the firm and can be supplied to any degree of sensitiveness down to one second of arc per 0.1 inch of run. In addition, a series of instructive notes are given on such subjects as tests of optical properties of telescopes; the application of stadia lines to instruments, diaphragms, circles and verniers; methods of observing with micrometer theodolites. Thus the catalogue forms a useful manual of instruments for the surveyor.

WIRELESS RECEIVING SET.—The Metropolitan Vickers Co., Ltd., is putting on the market a compactly arranged crystal receiving set specially designed for use with the broadcasting services that are soon likely to be started in this country. The set, which is intended for a range of about 15 miles, is priced at 4*l*. 10*s*., and consists of a tuner and crystal detector in a case, with a space to hold the head telephone set when not in use. The set requires only to be connected to the aerial, for the construction of which materials are supplied with the outfit. It is not clear whether the battery is contained in the case, but with this class of apparatus one or two cells only would be necessary. The tuner is conveniently arranged for working by a handle moving over a dial, and has no rubbing contacts, being formed by two coils, the relative angular position of which can be varied. For greater changes of wave-length, alternative condensers can be cut in and out. The crystals are chosen with great care, and a spare crystal is provided with each set. The company is also placing on the market a valve set at 23*l*. 10*s*., including batteries, aerial, insulators, etc. This is designed for ranges up to 50 miles and employs two valves, one detecting and the other amplifying. The batteries are contained in a separate box, and the whole of the leads for the telephone head set and the high-tension and low-tension batteries are brought to one plug, which can easily be detached from the set before the lid is closed. This automatically throws the valves out of operation. A loud-speaking telephone can be substituted for the ordinary head set at a slight extra cost. Both these sets will pick up wave-lengths from 300 to 600 metres, and we are informed that both have been approved by the Postmaster-General.

The Weights and Measures of India.

By C. A. SILBERRAD, President Indian Weights and Measures Committee

A COMMITTEE was appointed by the Government of India in the autumn of 1913 "to inquire into the whole question of the feasibility of securing the use of uniform weights and measures in India." It submitted its report[1] in July 1914, but further consideration of the matter was delayed by the war and subsequent political developments in India, and it was only in April 1922 that, after consultation with Local Governments, the final resolution on the report was issued. This in brief approved the recommendations of the report and left it to Local Governments to give effect to them so far as and in what way each thought advisable.

Like its inhabitants, the weights and measures of India are extremely diversified, but, like them, they are susceptible of a certain amount of classification. Doubtless originally the systems which came into use at the different centres were entirely independent, but with the centralisation of administration, the unification of the coinage, and the spread of railways a certain degree of systematisation has arisen, and the weight of the tola has been assimilated to that of the rupee (180 grains), and is recognised practically everywhere as a fundamental unit, the relation of which to almost all weights in actual use is known.

The system of weights most widely known is that in force on the railways. This consists of the seer of 80 tolas (of 180 grains each) and the maund of 40 seers, with the chatak of 5 tolas. This system is used almost to the exclusion of any other in the west of the United Provinces, the Panjab, except a tract in the centre and the districts bordering on the North-west Frontier Province, the Hazara district of the latter, Sind, Baluchistan, the north of the Bombay Deccan, and the greater part of the Central Provinces. In the Central Panjab, the southern portions of the United Provinces, Chota Nagpur, and practically all Bengal and Assam this system is in use in combination with various other seers—usually known as *kachchha* (*i.e.* imperfect) seers, consisting of a variable but always smaller number of tolas, usually 40 to 60. In Rohilkhand (United Provinces) and the western Panjab with the trans-Indus portion of the Frontier Province the most usual system is one in which the seer contains about 100 tolas, while in Gujarat that most commonly used contains 40 tolas.

In the eastern parts of the United Provinces and the greater part of Behar proper, with adjoining portions of Chota Nagpur, the popular systems are extraordinarily variable. They are based on some number of *gandas* (sets of four) of the local pice (copper coins). These are of two kinds, Gorakhpuri and Lohiya. The Gorakhpuri pice were coined at Butwal in Nepal, and like Lohiya pice consist of shapeless dumps of copper, the weight of which was variable when they were new, and has become much more so with use. A number of *gandas* of such pice was taken to represent the seer of the place concerned. That number would naturally represent a somewhat different weight when other pice were used, so some would be added or subtracted, and that new number would start a new seer. Matters were further complicated by the adoption of the rupee in some places as unit instead of the local pice, the same numbers being used. The numbers supposed to be equivalent to a definite weight vary considerably, a fair average is 100 Lohiya pice = 92 Gorakhpuri pice = 80 tolas. In the Gorakhpur district seers of 8, 8½, 11, 12, 13, 13½, 13¾, 14, 21, 22, 24¼, 25, 27, 27½, 28, 32, 36, and 40 *gandas* of such pice are reported, while with other seers the total number reported as in use in various parts of the district amounts to 42, not to mention several *pauseris* (literally five seers) weights to which there is no corresponding seer in use. The Lohiya pice are fully as variable, 121 separate *gandas* when weighed were found to give 60 different weights varying from 531 to 675 grams. The result is extraordinary confusion.

The *kachchha* seer of 32 to 36 tolas used in the central Panjab has a somewhat similar origin, this seer being supposed to be the weight of 36 *mansuri* pice, a coin coined in the Maler-Kotla state and of varying weight, the 36 averaging 33¾ tolas. Similarly in the north-west Frontier Province the Peshawari seer was supposed to be the weight of 102 Doadzashahi or Nanakshahi rupees, each of which was slightly heavier than the present rupee.

Lastly, there are the tracts where a small seer of 15 to 28 tolas is used to the more or less complete exclusion of any other seers. Thus in Bombay city the ordinarily used seer is of 28 tolas, and small seers of something near this weight are current throughout the southern Bombay Deccan, the Konkan, and west Berar.

Throughout these parts of India the table of weights is very similar. The chatak is always one-sixteenth of the seer; it is, however, known by other names—*e.g.* it is a *kanwa* in parts of Behar and Orissa, a *sharak* in the western Panjab, and an *anna* in Sind; while the sixteenth part of the central Panjab *kachchha* seer is termed a *sirsai*. In some tracts the chatak is divided into four parts, these are termed *kachha* in Bengal and *duko* in Sind.

The maund, though usually containing 40 seers, does not do so by any means always, the variations in this respect being by commodities as well as by localities. Thus in Cawnpore a dozen different maunds, containing from 41 to 63 seers (of 80 tolas), are in use for various kinds of merchandise, and in Bombay city seven maunds and 12 khandis. This latter is a weight supposed normally to contain 20 maunds, those in use in Bombay vary from 11 to 28 Bombay maunds (of 40 seers each of 28 tolas).

So far as they fall into this classification the Madras weights come under this head, as the standard seer for Madras contains 24 tolas and the larger seers are but little used, though the 80-tola seer is known through its use on the railways and by Government. The standard table is 3 tolas = one palam, 8 palams = one seer, 5 seers = one viss, 8 viss = one maund. But the palam is 6 tolas in Madras, varies from 3¾ to 15 in Malabar, and is ¼th pound avoirdupois in Tinnevelly. The viss too may sometimes be 6 seers, and maunds and khandis (usually 20 maunds) vary as greatly here as elsewhere. Certain places have other peculiar weights—*e.g.* the *thukku*, varying from 100 to 250 tolas, and the *tulam* from 800 to 1350. An interesting survival is the use of the Dutch pound (termed *rathal* and deemed equivalent to 42½ tolas) in Cochin. Similarly the British pound has given rise to a *rathal* of 38½ tolas, and in the parts of Arcot near Pondicherry the half-kilo to one of 42·9 tolas. The Madras weights are the most confused and complicated of all India, this being due possibly to the greater differences between the peoples composing its population, and to the fact that much of the Presidency never formed part of the Mughal Empire, and that consequently the basis of many of the weights was not the rupee but the pagoda or some

[1] Report of the Weights and Measures Committee, published by the Government of India. Government Central Press, Simla. Rs. 2.

other coin, so that the adoption of the rupee tola as a unit was more difficult.

The following table, showing the number of different seers reported to the Weights and Measures Committee in 1913-14 in each province, will give perhaps a clearer idea of the complexity and confusion of Indian weights than anything else

Province	Number of Seers equivalent to							Weights in Tolas of smallest and largest Seer.
	Less than 30 Tolas	30-50	50-70	70-90	90-110	Above 110	Total.	
United Provinces	4	21	11	21	30	13	106	18[illegible]—130
Bengal	1		7	19	10	6	43	16—189
Madras	12	2		13	2		29	20—105
Behar and Orissa	1	18	12	16	8	3	58	28—132
Panjab		15		4	8		27	30—105
Bombay	15	5	1	5		2	28	15—130
Central Provinces	3	2	1	-	3		11	21—100
Assam			2	6	4	2	14	60—120
N.-W. Frontier Province			1	3	4	2	10	50—154$\frac{1}{2}$
Baluchistan	.	.		1		..	1	80

Weights smaller than the tola are used mainly by jewellers and physicians, and the most fundamental unit for these throughout India would appear to have been originally the red and black seed of the *Abrus precatorius*, termed in Northern India the *gunchi*, and assumed to weigh one *ratti*. Other seeds and grains were also used, such as the poppy seed, the seed of the *Cæsalpinia sepiaria* and grains of juar (the greater millet), rice, wheat, and barley. The tola used in this table frequently differs from that of 180 grains, but is now usually connected therewith by being deemed equal to a definite number of rattis more (or less) than the standard tola. A very usual table in Northern India is—8 khaskhas (poppy seeds) = one chawal (grain of unhusked rice), 2 chawal = one jau (barleycorn), 4 jau = one ratti, 8 rattis = one masha, and 12 mashas = one tola. In Bengal, Behar, and Assam the *dhan* (grain of husked rice) takes the place of the *jau*. In Bombay and the Central Provinces 2 rattis make a *val*, which is held to be represented by the seed of the *Cæsalpinia sepiaria*, while in part of the Chanda district a grain of wheat serves this purpose. Throughout Behar, Bengal, Assam, and the greater part of the Central Provinces the jewellers' tola is usually 180 grains. In Northern India it is usually greater by from one to twelve rattis, the most usual values being two, three, or four rattis in excess. Occasionally, however, the gold tola is less than 180 grains. In Bombay it varies from 172 to 192 grains. In Madras jewellers' weights seem to vary almost from district to district, and the complications are innumerable. The seed of the *Abrus precatorius*, held to represent the weight *gundumani* or *guruginja*, is a frequent unit, but various obsolete coins (*e.g.* the fanam and the pagoda) and their fractions are in use, and the relations of these weights to the 180-grain tola usually but little known. As an example of the result of these multifarious measures it may be mentioned that silver is occasionally weighed in Madras by a table which is connected with the standard tola by the fact that 3399 of the *rattis* thereof are equal to 64 tolas! As a matter of fact, throughout India current silver coins are largely used as weights, though the larger jewellers frequently have well-made sets of weights representing the locally current tables.

There remains Burma. The weights of this province though showing some connexion with those of Madras, are fundamentally different. The universally current unit is the *peiktha*, usually known to Europeans by its Madras name of *viss*, which has been fixed by Government as 140 tolas (3·60 lbs avoirdupois), though as a matter of fact this "fixation" has had but little effect outside a few of the municipalities. It varies slightly, having apparently originally been really about 142[illegible] tolas, and was formerly held to be equivalent to 3·65 lbs. avoirdupois (or 141$\frac{17}{18}$ tolas). The *peiktha* is divided into 100 *kyat* or *gyat*, known to Europeans as *tikal*. This, it may be mentioned, is, so far as I know, the only truly decimal subdivision current anywhere in the Indian Empire.

For weights below the *tikal* the original table appears to have been 2 small ywès = one large ywè, 2 large ywès = one pè; 2 pès = one mú; 5 pès = one mat; 2 mats or 5 mús = one ngá-mú ("five-mú"), 2 ngá-mú = one tikal. Various seeds are used to represent some of these weights; thus, that of the *Abrus precatorius* is held to be equal to the small, and that of the *Adenanthera pavonina* to the large *ywè*, while the seed of the *Garcinia pedunculata* is occasionally deemed equal to 8 large *ywès*. This table was complicated by the fact that, owing to intercourse with India, the *tikal* was divided also into 16 parts, equally known as *pè*, and then four of these went to the *mat*. Further complications were introduced by the application of the same series of subdivisions to the tola of 180 grains, as fundamental unit, in place of the *tikal*, while in the Ruby Mines district the *ratti* is thus subdivided. The result, needless to say, is extreme confusion.

British (avoirdupois) weights are a good deal used in Bombay city and some of the big towns of Bombay, Berar, and the west of the Central Provinces, and in a considerable number of places in Madras, but practically only in large places and by the larger establishments. Not infrequently the nearness of the pound weight (38$\frac{8}{9}$ tolas) to the half of the 80 or the whole of the 40 tola seer leads to mistakes, or even to deliberate fraud. Any knowledge of the metric system is confined practically to the neighbourhood of Pondicherry.

Only the more important variations have been discussed; to give anything like a complete list would be far beyond the limits of space admissible. The Weights and Measures Committee of 1913-14 prepared a complete list showing for each district in India and Burma all weights and measures reported to them as in use. It forms a volume of some 500 pages. Enough has, however, been said to show the extreme confusion in weights that exists in many parts of India.

Apart from the use of seeds to represent weights there are few items of special interest. In Upper Burma before the annexation, weights based on the system sanctioned by the King were always made in the form of the *hentha* (known in India as the Brahmini duck). Although in many parts of India well or fairly well made metal weights are in use, often the actual weights consist of lumps of metal or stone, while smaller weights are made out of buttons, etc. Even where cast-iron weights are in use it will frequently happen that there is no indication as to the precise seer, etc., which is deemed to be represented. Thus two or more iron seers of identical appearance but different weights may be found in use in the same town, and sometimes even in the same shop.

In a few places, and these by no means the more advanced, locally made steelyards are used; thus in Cuttack the *bisa* is a steelyard with movable fulcrum used to weigh articles up to 4 or 5 pounds. Similar steelyards, called *tul* or *tulachoni*, are in use in several districts in the Brahmaputra valley. In Burma, steelyards with fixed fulcrum (known as *le-dan* or *taing-tzu*) are regularly used by the Chinese, but

looked askance at by the Burmans, who sometimes find themselves outwitted by the Chinaman when it is used. This instrument, frequently well made of bone or ivory, has one movable weight and two or three points of support, with scales marked on the rod corresponding to each point of support.

Measures of Length.—As almost throughout the world the cubit, or distance from the elbow to the tip of the middle-finger, was the original fundamental unit. This is subdivided into spans, fist-breadths, and digits, and also into sixteenths. A very usual table in Northern India is: 3 jau (barleycorns) = one angul (digit); 3 angul = one girha; 4 angul = one mushti (fist-breadth); 4 girha or 3 mushti = one balisht (span); 2 balisht = one hath (cubit); 2 hath = one gaz (yard).

The names of the various measures of length naturally vary in different parts of the country; thus the yard is a *val*, *var*, or *war* in Bombay and the Central Provinces, and a *gaik* in Burma; the cubit, known as *hath* throughout Northern India, is a *mura* or *mulam* in parts of Madras and a *taung* in Burma. The *girha* is a *visam* in Madras, but corresponds to no measure in Burma. The *balisht* of Northern India is the *bighat* of Bengal, the *jana* of parts of Madras, and the *htwa* of Burma; but the general table is very similar throughout the whole country. The *gaz* (*gaj*, *var*, or *gaik*) varies considerably from place to place, and for different articles, and altogether the number of variants is great; the great majority, however, are within three inches of the British yard, but there are yards in use as long as 48 in. and as short as 10 in., but such are exceptional. To a greater or less extent all are being assimilated to the British yard of 36 in., and in fact many are known by their length in sixteenths (*girha*) of that measure. The foot and inch are but little known, the yard being almost always subdivided, for practical purposes, into 16 *girha*.

The most important of other yards are:

(i.) That based on the *murwan* or *morni* (crooked) *hath* of approximately 24 in. This cubit was arrived at by measuring from the elbow round the tip of the outstretched middle-finger and back to the knuckle; it gives rise to a yard of 40 in. to 48 in., and the British yard is deemed equal to 1½ *morni hath*. It is in use in several districts of the Panjab near the Indus and the adjacent parts of the Frontier Province. It is divided into sixteenths (known as *sharak* or *tasu*) and also into twentieths, which are called *girha*.

(ii.) The Peshawari yard of 38 in. to 38¾ in., of which the British yard is deemed to be 15 *girhas* (*i.e.* 15/16ths). It is used throughout most of the Frontier Province.

(iii.) The *Imarati* or *Mi'mari gaz* (masons' or carpenters' yard). It is still used fairly widely in the north-western part of the United Provinces and the adjacent parts of the Panjab. Its usual length is 33 in., and it varies from 32½ in. to 34 in. It forms part of a special table used in the building and carpentry trades. This is: 4 pain (or 2 sole) = one sut; 4 sut = one pan; 4 pan = 1 tasu; 24 tasu = one imarati gaz. This table is however sometimes applied to the British yard, giving rise to a *tasu* of exactly 1½ in. This yard is probably identical with the *tachumulam* of the southern districts of Madras, which is 33 in. in length and used by carpenters and masons only. In the South Arcot district there is also a special "architectural inch" of 1½ in. British, 24 of which make the "architectural yard." In Bombay city yards of 32 and 24 *tasu* are occasionally used for measuring cloth, this *tasu* is 1⅛ in. British measure. Beyond the similarity of names of the subdivisions there would appear to be no connection.

(iv.) The *Ilahi* or *Akbari gaz*, originated by Akbar to represent one pace for purposes of land measurement, and at first 33½ in. in length, but now varying from 31½ in. to 40 in. It is over much of Northern India the basis of many indigenous systems of land measurement.

On the Malabar coast the yard is to some extent replaced by the *kole*, a measure of similar length, which consists of 24, or in places of 26½, *angulams* (or *virals*), which appear to be the length instead of the breadth of a finger joint, inasmuch as one *angulam* is held exactly to equal the diameter of a rupee or 1⅛ in.

Apart from the measures used for measuring land and distance there are practically no measures of any importance larger than the yard. Those for land measurement are closely connected with measures of area and will be considered therewith. Measurements of distance are usually vague. The normal indigenous unit is the *kos* (or in Madras the *kros*). Though supposed to be 4000 cubits it really has little, if any, connexion with that unit and varies from 1¼ to 3 miles. The corresponding unit in Burma is the *daing* or *taing*, supposed to contain 7000 cubits, but in reality equally vague. With the construction of roads and railways and the indication of miles and furlongs thereupon, these measures are now almost universally known and used. A somewhat unfortunate complication has, however, been introduced into the Panjab by the invention of a Canal "mile" of 5000 feet divided into five equal parts, each of which (from the shape of the "¼th-milestone" or *burj*) is termed a *burji*. Somewhat interesting is the introduction of new measures of length by reason of the way in which land is subdivided in the Canal colonies into *marabbas* (squares) and *killas* of 1100 ft. and 220 ft. square respectively. The lengths of the sides of these square areas are becoming known as measures of length under the names of the areas.

Most frequently however distances are referred to by the average villager as "the length of a field," "a gunshot," "the distance to which a man's voice will carry," etc.

Measures of Area.—There can be little doubt that the first measures of area depended on the amount of work involved in cultivating the area concerned, or the amount of seed required to sow, or produced by it. Thus the bigah, the most widespread unit of area, is said to have originally represented the area a pair of bullocks could plough in a day. Other units are defined as the area a pair of animals could maintain under cultivation throughout a year, or that they can harrow or sow in a day, or that a man can weed in a day. Many units are based on the area sown with some stated quantity of seed; in rice-growing areas by the number of paddy plants required for planting it, or as the area which a man (or sometimes a woman) can plant in a day, and so on. Another measure used in some parts is the area which can be guarded from the depredations of wild animals by one watchman on a raised platform. In Baluchistan a common measure of land is the area which can be irrigated in 24 hours.

These methods of estimating areas are still widely used by the cultivators themselves in the less thickly populated areas, such as most of the Central Provinces, Burma and Chota Nagpur, and parts of Bombay, Madras and Assam and the Himalayan tracts.

In the more densely populated parts of the country, where the value of the land is greater, a more definite method has been evolved. This throughout almost the whole of both India and Burma seems to have been based on a square each side of which is a certain number of paces, but which is now always expressed in terms of cubits. The length of this unit is extremely variable, but it would appear that in selecting a length the simplest that could be expressed conveniently in both cubits and paces was originally taken. Thus many of these units are near to 5

cubits, which, taking the cubit at 18 in., is equal to three paces of 33 in. each. This unit length has many names: in the United Provinces it is termed a *latta* or *gatha*, and the standard (so far as there was one) was three *Akbari gaz* (of $33\frac{1}{2}$ in. each). The standard most often recognised by Government, however, is of 66 in., so that 20 equal a chain of 55 yards. In the Panjab, the Frontier Province, and Sind the corresponding unit is the *karam*, the most important one being 66 in. in length. In Behar and Orissa it is known as the *bans*, *lagga*, *padika*, or *nal*, and usually varies between 6 ft. and 12 ft. In Bengal it is a *dhan*, *danda*, *nal*, or *katha*. In Assam a *nal*, *tar*, or *bes*. In Bombay proper a *kathi*, and in Sind a *kano*; in Madras a *nolo* (Ganjam) or *badda* (Nellore), and in Burma a *ta* (= seven cubits or $10\frac{1}{2}$ ft.). The actual area arrived at by this method is, however, most variable, and though the unit length seems to have originally been about three paces it may, as a matter of fact, be apparently anything from one to five. The more valuable the land and the more powerful the landowner the smaller is the *laggi*. A not infrequent method of raising rents was to shorten the length of the *laggi*, the "rent per bigah" remaining nominally the same for the smaller resultant bigah. Many riots have been caused by differences of opinion between landlord and tenant as to the correct length of the *laggi*. The square *laggi* has many names: in the United Provinces it is usually a *biswansi*, in the Panjab a *sirsahi*, in Behar a *dhur*, in Bombay a *kathi*, Assam a *rekh*, Burma a *palagwet*, and so on. Though it is almost always the four-hundredth part of the bigah (or corresponding unit), the intermediate subdivisions vary. The most general intervening unit is one consisting of 20 square *laggis*, known most widely as a *biswa* or *katha* ("*cotta*"). But in Orissa 16 of the smallest units make a *guntha*, and 25 *gunthas* go to the *man* (which corresponds to the bigah elsewhere). In the Panjab, where the square *karam* is known as the *sirsahi*, 9 of them go to the *marla*, 20 *marlas* equal one *kanál*, and 4 *kanáls* one bigah. Here two bigahs make a *ghumaon*, which has been standardised as one acre. This table holds over the western Panjab, Sind, and the Frontier Province. In Burma there are two large units—the *pègadi* (or "public" *pè*) containing 625 square *ta* (or *palagwet*), and the *min-pè* of 35 *ta* $2\frac{1}{2}$ *taung* square or 1250 [illegible] *palagwet*, treated for practical purposes as exactly equal to two *pègadi*.

In eastern Bengal the unit length is often used somewhat differently, the unit area being sometimes rectangular. Thus in Dacca and Maimansingh a common unit is the *káni*, a variable rectangle, but most frequently one the sides of which are 12 and 10 *nal*. The *pakhi*, another frequently used unit, appears to be practically only another name for the *káni*.

Though the system is so similar throughout the country it has not resulted in any uniformity; in fact, the bigah and connected measures are almost as indefinite as the older measures previously mentioned. Thus in the United Provinces no less than 58 bigahs, varying from $\frac{1}{10}$th to one acre, are reported. In Champaran district (Behar and Orissa) the *laggi* varies from 10 ft. $10\frac{1}{2}$ in. to 17 ft. $5\frac{1}{2}$ in. In Dacca the Settlement Officer had to prepare more than 100 conversion tables to reduce the local measures of area to the acre. In much of Madras the indigenous systems appear to have had other origins; thus in Madras city the *cawnie* of 1·32 acres is still used—this is equal to 20 *manai* or "grounds," the *manai* having originally been defined as the area sufficient for a small Indian house. Elsewhere the *gorru*, a measure based on the area a pair of bullocks can plough, is used; it is about $3\frac{1}{2}$ to 4 acres.

There are numerous other units of area in use in various parts of the country, and the variations of those bearing the same name are almost innumerable, but there would seem to be little purpose in giving further details.

When precision is necessary in dealing with areas which are of such vital importance to rent law and the land revenue, two methods have been adopted. Either the bigah has been standardised over a certain area or else the British acre (divided either into roods and poles, or more usually into one-hundredths) has been used. The number of different "standardised" bigahs actually adopted in the Settlement records is very great; thus in the Gorakhpur district of the United Provinces no less than nine were used. In many parts of the country the acre and its hundredth parts (generally termed "decimals," or in Burma "dathama") are becoming well known. In the Panjab Canal colonies two new units have been introduced: the *killa* of 220 ft. square and the *marabba* (square) of 1100 ft. square, equal to 25 *killa*, being respectively equivalent to 1 and 25 acres. In short, for all purposes where exactness is required either the acre and its subdivisions or some standardised indigenous measure is now used.

Measures of Capacity.—Contrary to what is sometimes alleged, measures of capacity for grain and such like articles are very widely used throughout India, the only tracts where they are practically non-existent being the greater part of the United Provinces (excluding the extreme east and south-west), most of Behar proper, and the eastern Panjab. It is true that in much of the rest of India they are mainly used in rural areas and the smaller towns and for retail and local transactions, but even so their use is widespread and certainly affects the great bulk of the people. In Burma, and to a less extent in Madras, they are of universal importance, forming the basis of large transactions. For some reason, or possibly by pure coincidence, their use is more widespread in the rice-growing areas, though by no means excluded from the rest of the country.

The unit measure of the series in use is usually defined as a measure containing a certain number of the chief current local unit of weight of the predominant grain. Sometimes a definite weight of a mixture of several (8 or 9) kinds of grain was used to fix the size. A picturesque variant to this rule occurs in the Khasia and Jaintia hills (the inhabitants of which were head hunters), where the size of the standard measure was fixed as being convenient to hold a man's head. Measures are generally used "heaped," rarely (though occasionally) "struck." As there is no uniformity in the cross section of measures supposed to contain equal quantities this increases the variations. The measures themselves are made sometimes of wicker-work, at others of wood or metal, and may be cylindrical, rectangular, prismoidal, hemispherical, or more or less globular—*i.e.* in the shape of a sphere with considerably less than the upper hemisphere removed. The wicker measures especially are liable to increase in size with age. Save in Burma, Madras, and a few of the larger municipalities in the Central Provinces and Berar, no attempt has ever been made to standardise them, and there has never been anything corresponding to the unifying influence of the railway seer to assimilate the measures of different places.

The chief measure of a place is generally one containing from one to five local seers of some grain, and there are various multiples and submultiples of this, the larger ones being merely measures of account. It has already been seen how numerous are the local units of weight—the reasons just given make those of capacity even more variable. The units themselves, and the names and mutual relations of their multiples

and submultiples, vary from district to district, and, indeed, are very far from being uniform throughout a district. As their use is largely confined to local transactions this variation is of less importance, for the normal customers of each market are fully aware of the measures in use there. It would be of little interest to give the innumerable names of these measures; one example of their variability will suffice. The *gauni* is a widely used measure in Orissa; the Balasore district reports the use of 18 different *gaunis*, said to contain anything from 1 to over 8 seers of paddy. In Cuttack its limits are somewhat closer—1⅜ to 7 seers—while in Puri they are said to be from 2 to 8, and 9 different *gaunis* are reported as in use. The actual measure is made of wicker.

The standardised measures of Madras and Burma call for more detailed comment. In Madras there are two, known respectively as the Madras type measure or *padi* and the Madras type seer; they are defined as holding respectively 120 and 80 tolas of second sort rice when "struck" or 132 and 88 when "heaped." Of water they contain 62.5 and 41.7 oz. One or other is used throughout a considerable portion of the Madras Presidency, but by no means to the exclusion of numerous other measures which may or may not bear a definite relationship to them.

It is, however, in Burma that capacity measures are of greatest importance, as it is by the *tin* or "basket" that rice is almost universally bought and sold wholesale, and by its submultiple measures retail. The table of measures most frequently used is: 2 lamè = 1 zalè, 2 zalè = 1 hkwet, 2 hkwet = 1 pyi or byi (or with the initial particle ta—ta byi, whence "tubby"), 2 pyi = 1 sayat, 2 sayat = 1 seik, 2 seik = 1 hkwe, and 2 hkwe = 1 tin or basket. It is an interesting comment on the desire for a standard measure that the tin of "Milkmaid" brand condensed milk has become universally recognised as representing one *lamè*; the Nestlé's tin as one *zalè*, and the tin containing preserved herbs as 3½ *lamè*. In origin the *lamè* is said to have been two handfuls, and the basket to have come into existence as being the amount of unhusked rice a man could conveniently carry at one time. The Burmese Government appears to have made some attempt at standardising it, and the British Government has more or less recognised as the standard basket one containing 9 gallons, other baskets being defined in Government reports in terms thereof. The baskets in ordinary use throughout the country vary a good deal, being usually somewhat smaller than 9 gallons. Most, however, contain between 8 and 9 gallons. The basket used by the rice-millers of Rangoon, Bassein, and Moulmein is as a rule a cylindrical wooden vessel, 24½ in. or 25 in. in height and 14½ in. or 15 in. in diameter. One of these measures is taken to measure a consignment of paddy, and every now and then a basket is weighed—usually 5 or 6 per 10,000. The price is fixed at so much per 100 baskets of 46 lb., with the proviso that 2½ per cent. more be paid for every pound the average basket weighs in excess of 46, while for every pound it weighs less 2 per cent. is deducted. For other produce for export, baskets containing definite weights are used, and trade in them is really by weight. But rural trade is almost entirely by measure.

There are practically no true liquid measures anywhere; occasionally one of the dry measures will be used, but the usual way of selling liquids is by weight, a measure containing a definite weight of the specific liquid for which it is used being frequently used for convenience.

We thus find that throughout the country, with the exception of Burma and to a less extent of Madras (here only as regards weights below the tola), the tola of 180 grains or the weight of the rupee is a universally recognised unit, and to an almost equal extent the "railway" seer of 80 such tolas is at least known and over a large extent of the country actually used. The identity of the weight of this tola and of the rupee is a most important point to remember, as it makes it almost compulsory to change the weight of that coin if any system not based on this tola be introduced. This is a proceeding very liable to be viewed with great suspicion by the less educated portion of the community. For a measure of length the British yard is almost universally known and very widely used. As a measure of area the acre is fast becoming the only really definite one. Measures of capacity are various, but dependent on measures of weight.

Accordingly the majority of the Weights and Measures Committee recommended the adoption of the "railway" seer of 80 tolas (each of 180 grains), the British yard and the acre as fundamental units, and suggested the standardisation of suitable measures of capacity at the nearest suitable multiple of the bulk of 1¼ seers of water, this being approximately equivalent to the bulk of a seer of wheat. This conclusion, negativing any approximation to a decimal system, was certainly viewed with regret by myself, but the binary system and the rupee-tola unit are so firmly rooted in the country that it seemed inadvisable to attempt to change a method which was at least equally good for the ordinary transactions of everyday life for one the advantages of which are apparent mainly in foreign trade. The fact that practically no progress towards adopting the metric system in England has been made (*vide* NATURE, vol. 110, p. 29) is of considerable interest in this connexion, for when such is the case in a highly educated and intensely commercial country, where the proportion of foreign trade is probably higher than anywhere in the world, would it have been justifiable to recommend the compulsory adoption of the metric—or, in fact, of any decimal—system for India?

School Instruction in Botany.[1]

IT is, we believe, a misfortune that so large a proportion of teachers of botany in schools know little practically of the cultivation of plants. It is, indeed, not unusual for simple laboratory experiments involving the use of growing seedlings and plants to come to an untimely end owing to lack of precautions which would be observed by every practical gardener. The uncertainty of success of even simple experiments in such unskilled hands is no doubt in part responsible for the fact that school botany is still so largely concerned with taxonomy—which only the trained botanist can appreciate fully—and so little with those fundamental aspects of plant biology which should be of interest to all.

A general understanding of the significance of green plants in relation to the food problem, of the conditions controlling the growing of crops, and of the differences between such "artificial" vegetation and the natural vegetation of the countryside, with similar matters of fundamental importance, should be as much a part of general educational equipment as is the knowledge that the earth revolves round the sun, or the ability to use decimal notation.

[1] The Botany Gardens of the James Allen's Girls' School, Dulwich. Board of Education. Educational Pamphlet No. 41. Price 2s.

Those who desire to see biology take its proper place in general education, as also others more directly interested in the teaching of botany in schools, owe a debt of gratitude to Dr Lilian J. Clarke of the James Allen's Girls' School, Dulwich, for a practical demonstration of how much can be done within the rather narrow limitations of a school curriculum to make botany a "live" subject, and also for the creation of a school botany garden in many respects unique both in design and in the manner in which it is utilised in the teaching work

In a pamphlet before us, the publication of which has been greatly delayed by post-war conditions, Dr Clarke gives a stimulating account of the history and organisation of the school botany gardens and the teaching work associated with them. We have no doubt that this report of an interesting experiment in science teaching will serve the purpose intended by the Board and be helpful to other schools which give special attention to the teaching of botany. To quote Dr Clarke "Our main object in developing the gardens has been to make the teaching of botany thoroughly practical by closely associating indoor with outdoor work . The gardens have been of great assistance in carrying out the method of studying botany by direct observation and experiment . they are, in fact, outdoor laboratories."

Attention may be directed to two features of special interest in these botany gardens. One is the provision of vegetable plots in sole charge of the pupils themselves. Certain obvious difficulties must be overcome in order to make possible the inclusion of garden work as part of an ordinary school routine, and it is proof of able administration on the part of the science staff, and willing work and co-operation on the part of the girls themselves, that these plots showed a working profit during the period 1912-15 Used in this way, garden work stimulates interest in plant life and affords a reasonable basis for lessons in photosynthesis and the essential features of plant physiology.

A more unusual feature in the gardens, and one of great educational value, has been the construction of a number of special areas, each designed to provide the conditions requisite for a characteristic type of vegetation Among these are fresh-water and salt-water marshes, a pond 34 ft by 23 ft, a pebble beach, a peat bog, and soil conditions favourable for the growth of chalk-loving and heath plants, as well as the successful reproduction of natural vegetation units such as an oak wood No better introduction to the study of plant ecology can be imagined than these attempts to reproduce the essential conditions of special habitats with the subsequent collection, naming, planting, and care of the appropriate plant species.

The value of science teaching in schools would be greatly enhanced were more attention given to linking up different groups of scientific facts and to bringing them into touch with other subjects in the school curriculum and with the facts of ordinary life. Botany teaching as described in this report appears to offer an opportunity of doing this For example, it is not difficult to link up the recognition of vegetation units such as those referred to above with the teaching of geography and history

No mention is made in the report of the utilisation of the botany gardens for the observation of animal life, although it is clear that development is possible along these lines also The phenomena of metamorphosis in frogs and butterflies, and the inter-relations of plant and animal life as shown by the association of certain caterpillars with specific food plants may be cited as examples, as well as the opportunity afforded for observations on the ecology of animals.

University and Educational Intelligence.

DR. KENNETH FISHER, senior science master at Eton College, and formerly assistant master at Clifton College, has been appointed headmaster of Oundle School, in succession to the late Mr. F. W. Sanderson.

THE Council of the City and Guilds of London Institute in their report for 1921 reviews the history of this body's work from its inception in 1876. The report shows that the aggregate amount of the contributions by the City companies to the Institute's funds exceeds one million pounds. Of the several undertakings maintained wholly or in part by the Institute, the most important is the City and Guilds (Engineering) College, now constituting the engineering section of the Imperial College of Science and Technology Of the degrees in engineering conferred by the University of London in the past twenty years, nearly half, of honours degrees more than half, were won by students of this college The total number of students in 1920-21 was 609, of whom nearly half were taking electrical engineering The Finsbury Technical College, which it was proposed to close last year owing to financial difficulties, has now been placed under a delegacy as a grant-aided institution subject to the regulations of the London County Council Technological examinations conducted by the Institute were in 1921 held in 67 subjects in 316 centres, including many in India and other parts of the Empire overseas. The number of entries was nearly eight thousand.

A PROJECT for an international congress of all universities, both state and independent, of all countries, is to be elaborated by a sub-commission of the commission on intellectual co-operation set up by the League of Nations, consisting of Profs Gilbert Murray and de Reynolds (Berne), A de Castro, director of the faculty of medicine in the University of Rio de Janeiro, M J Destrée, ex-minister of sciences and arts of Belgium, and Dr R A Millikan, director of the Norman Bridge laboratory of physics at the technological institute of California This sub-commission will begin by examining, with due regard to the sovereign right of nations to legislate in matters of education and to university autonomy, the questions of exchange of professors and of students, equivalence of university studies and diplomas, the institution of international bursaries and vacation courses, and a central bureau of university information. In making these proposals the council of the League appears to have overlooked those two very efficient existing organs, the Universities Bureau of the British Empire and the American Institute of International Education, which were established by the universities themselves and are actively engaged in furthering these very objects. Another sub-committee, consisting of Madame Curie and M Destrée and a certain number of specialists to be co-opted by them, is to study the organisation of international bibliography and the question of establishing international libraries on the basis of a convention entitling them to receive copies of all published works.

AT the fifth annual meeting of the American Council on Education reports were presented showing that under the able direction of Dr. S. P Capen this body has accomplished much useful work and has in hand enterprises of far-reaching importance in connexion with questions of educational policy. It has played a leading part in the recent development of Franco-

American educational relations, both through its management of exchanges of scholarships and fellowships, and through collaborating with the French Ministry of Public Instruction in working out equivalencies of French and American academic records. At present 50 scholarships are offered through the Council by American universities and colleges to French students, while 40 are offered by French universities and lycées to Americans. As regards the establishment of what the French call "équivalences de scolarité," the Council's standing committee on international educational relations prepared a report (published last January) which has been accepted by the Conseil Supérieur de l'Instruction Publique as the basis for the admission of American students to candidacy for the State doctorates. The council has also a standing committee on College Standards which is engaged in devising means for effecting a general unification of procedure on the part of the several national and sectional accrediting bodies, and it has formulated already a list of basic requirements for admission to a list of accredited colleges. Another standing committee is busy with the question of tariffs on educational supplies, another is about to present a first instalment of its report on educational finance; another is investigating how the established principles of "academic freedom" may best be safeguarded and their general application be promoted in the face of threatened restrictions by legislation of the freedom of teaching and investigation; while another is to undertake a registration in the form of a directory, of college and university teaching personnel, to include at the outset at least 25,000 names.

THE programme of lectures and classes for teachers during the session 1922–23, organised by the London County Council, has recently been issued. Teachers from outside the London area are admitted to the lectures on payment of a small additional fee. The handbook is drawn up on similar lines to those of previous years, the lectures being divided into groups according to subject. Among the science lectures there are several interesting courses, among which are the following: Prof C Spearman and the Rev F Aveling, ten lectures on the experimental investigation of children; Mr Cyril Burt, three courses of lectures on psychology and education; Prof O W Richardson, ten lectures on modern views of matter and radiation, Prof. F E Fritch, five lectures on the vegetation of the London area, Prof A Smithells, one lecture on the atom, Sir William Bragg, five lectures on the constitution of matter, Dr R S Clay, ten lectures on science in elementary schools, Mr A L. Leach, eight lectures on the geology and geography of the London district, Prof J. Arthur Thomson, three lectures on the progress of evolution; and Prof T P Nunn, six lectures on Einstein's theory of relativity and its educational bearings. In addition to these courses, there will be four special lectures—on teaching children astronomy, by Sir Frank W. Dyson, on the significance of crystal analysis, by Sir William Bragg, on the relation between the health and character of the school child, by Prof Karl Pearson, and on the drama of animal life, by Prof J Arthur Thomson. The value of these special lectures by recognised authorities on their own subjects can scarcely be over-emphasised. Courses are also being organised in geography and in the teaching of arithmetic and mathematics. Copies of the handbook of the lectures, with application forms, can be obtained from the Education Officer at the County Hall, Westminster Bridge, S.E.1.

Calendar of Industrial Pioneers.

September 3, 1854, Henry Fourdrinier died.—Born in Lombard Street, London, in 1766, Fourdrinier, with his brother Sealy, succeeded to his father's business of paper-making, and at the beginning of last century endeavoured to introduce the continuous paper-making machine invented in 1799 by the Frenchman, Louis Robert. He spent some 60,000*l* improving and making new machinery, but ultimately became bankrupt. The subsequent success of the paper-making machine was largely due to Bryan Donkin, but Fourdrinier's pioneering work was acknowledged in 1840 by a Parliamentary grant to him of 7000*l*.

September 3, 1874. Sir John Rennie died.—The first British civil engineer since the days of Sir Hugh Myddleton (1560–1631) to receive the honour of knighthood, Rennie was trained under his father, the builder of Waterloo Bridge, and was responsible for the building of London Bridge and the completion of the Plymouth Breakwater. He was engineer to the Admiralty, carried out many important harbour works, and in 1845–1848 was president of the Institution of Civil Engineers.

September 3, 1895. Ralph Hart Tweddell died.—One of the pioneers in the application of hydraulic pressure to machine tools, Tweddell brought out his hydraulic rivetting machine in 1866. His methods reduced the cost of rivetting to one-seventh that of hand work. Used first by Armstrong at Newcastle in 1871, Tweddell's hydraulic machines were extensively adopted three years later in the French dockyard at Toulon.

September 5, 1885. Walter Bentley Woodbury died.—Originally an engineer, Woodbury spent some years in Australia, Java, and Batavia, and became known for his successful work with the collodion process in photography. Returning to England in 1863, he invented the Woodbury-type process and patented many improvements in connexion with photography.

September 6, 1842. Jean Baptiste Van Mons died.—The founder of the *Journal de chemie et de physique*, and a prolific writer, Van Mons at a time when the nations of Europe were at enmity, performed a valuable service by propagating abroad a knowledge of the discoveries of Lavoisier, Volta, Vauquelin, Chenevix and others. He was born in Brussels in 1765, became a pharmacist, and for twenty years was professor of chemistry and agriculture in the University of Louvain.

September 7, 1870. Cowper Phipps Coles died.—Flag-lieutenant to Admiral Lyons during the Crimea War, and in 1855 captain of the paddle sloop *Stromboli*, Coles first became known for his construction of a gun raft. Taking up the study of naval architecture he carried out experiments on mounting guns in cupolas, and he was afterwards responsible for the design of the ill-fated turret vessel H M S *Captain* which capsized off Cape Finisterre on the night of September 7, 1870, Coles being on board at the time.

September 8, 1761. Bernard Forest de Belidor died.—Known principally for his writings on hydraulics, Belidor as a French military engineer made many experiments on the explosive power of gunpowder, became inspector of artillery and held a post in the arsenal at Paris. His "Architecture Hydraulique," long regarded as a standard work, was first published in 1753, while Navier published a new edition with notes in 1819.

E. C. S.

Societies and Academies.

PARIS.

Academy of Sciences, August 7.—M. G. Bigourdan in the chair.—B. **Baillaud**: A new transit instrument recently installed at the Paris Observatory.—S. **Winogradsky**: The supposed transformation of the nitrifying ferment into a saprophytic species. A criticism of the views of M. Beijerinck on the nitrifying organism.—M. **Abramesco**: Developments in series with two complex variables following the inverse of given polynomials.—D. **Yovanovitch**: The chemical properties of mesothorium-2. Radioactive barium chloride is precipitated by hydrochloric acid: the precipitate contains mesothorium-1, thorium-X, and radium. The mesothorium-2 is precipitated as hydrate, and freed from thorium B and C by treatment with sulphuretted hydrogen after adding a little lead and bismuth. Its chemical properties resemble those of lanthanum.—J. **Orcel**: The chemical composition of aerinite.—J. **Barthoux**: Minerals of the Oudjda region (Morocco). The following minerals have been found in a lead mine near Oudjda: galena, vanadinite, pyromorphite, wulfenite, cerussite, dolomite, calcite, and aragonite: details of the crystal forms are given.—Aimé **Azam**: The constitution and origin of the sediment of the plain of Caen called *rougeauts* and *fauvels*.—J. **Voicu**: The influence of humus on the sensibility of *Azotobacter Chroococcum* towards boron. In a culture medium without humus the effect of boron on the nitrogen assimilated is insignificant, but if humus is added to the culture the toxic action of boron is marked, and the amount of nitrogen fixed is reduced.—René **Maire** and E. **Chemin**: A new marine pyrenomycete.—F. **Granel**: The structure and development of the pseudobranchia of the teleosteans.—Paul **Portier** and Marcel **Duval**: The variation of the osmotic pressure of the blood of the eel as a function of modifications of the salinity of the external medium. The osmotic pressure of the blood serum of the eel living in fresh water is much higher than in the carp: when the salt in the water is changed from 0 to 39 parts per 1000, with corresponding change in the freezing-point from $-0^\circ.02$ to $-2^\circ.22$, the freezing-point of the serum changes only from $-0^\circ.63$ to $0^\circ.83$, and the fish is not prejudicially affected. In salt solutions of higher concentration than sea water the eel dies.—Mlle. F. **Duboc**: The action of tribromoxylenol on tubercle bacilli.—A. **Trillat**: The influence of humidity and vesicular state on the diffusion in air of drops containing micro-organisms. From 98 per cent. to 99.5 per cent. of the liquid dust produced by an ordinary pulveriser fall within a few metres of the point of origin. But of the remainder, some drops are so small that they remain in suspension, especially if the air is nearly saturated with moisture, and may travel considerable distances. That micro-organisms may be carried in this way has been proved by exposure of Petri dishes, and also by experiments with animals (mice).

MELBOURNE.

Royal Society of Victoria, June 8.—Mr. F. Wesiwould in the chair.—Reuben T. **Patton**: On the drying of timber. An examination of moisture distribution in oak from winter to autumn seems to indicate that the moisture content of the heartwood is constant. Other trees, however, gave very extraordinary moisture distributions, and these emphasise the need for further investigation. Diffusion constants were obtained for some common timbers, and these show that oak has the lowest constant while pine has the highest. A study of the diffusion of moisture through the wood goes to show that the fibre saturation theory does not hold. Work with cubes of green timber tends to show that drying from the end is about five times as fast as from a radial face. Thickness has no influence on the rate of drying. The curves of loss for a series of thicknesses form an envelope. The maximum temperatures and minimum humidities occurring in this state give very favourable drying conditions. Only at a humidity of 2 per cent. was the rate of drying adversely affected. The more rapid the drying the greater is the amount of shrinkage.—S. R. **Tovey** and P. F. **Morris**: The contributions from the National Herbarium of Victoria, No. 2. The paper contained a description of *Teucrium racemosum*, R.Br., var. *polymorpha*, Tovey and Morris. The variety differs from the type *T. racemosum* in having the stamens inserted in the corolla and the stigma only slightly exserted. Three new records of recent introductions were also given, viz.: 1. A deciduous ornamental tree *Paulownia tomentosa*, Steud. (*P. imperialis*); 2. *Scorzonera laciniata*, Lt.: this plant is sometimes cultivated for its tapering root; 3. *Solanum triflorum*, Nutt., has made its appearance; it somewhat resembles the common Black Nightshade. The leaves are deeply cut (pinnatifid), the berries are about the size of a small cherry. In America the berries are considered poisonous. The active constituent is Solanin. The plant has been proclaimed under the Thistle Act for the whole State. The remainder of the paper consists of records of additional regional distribution of plants, also corrections in accordance with article 48 of the Vienna Botanical Congress (1905) and other notes of interest.

CAPE TOWN.

Royal Society of South Africa, July 19.—Dr. J. D. F. Gilchrist, president, in the chair.—K. H. **Barnard**: Maps illustrating the zoological aspects of Wegener's disruption hypothesis. Stress was laid on the fact that on this hypothesis the land bridges connecting the southern continents into an enormous more or less equatorial continent were not required; that on the contrary the greater part of the old polar Gondwanaland was still in existence at the present day, and had never been beneath the sea since palæozoic times. Consequently the distances over which such groups as, e.g., the Acanthodrile Worms, Peripatopsidæ, Acavid Landshells, Cystignathid Frogs had had to travel was minimised. The extremities of these continents, hitherto regarded as peripheral, and containing primitive types driven thither by more specialised rivals, are seen to be really portions of the centre of Gondwanaland. The primitive and generalised types have always been approximately where we find them to-day, and their dispersal has been hindered and restricted, other than by physical causes, by the appearance of higher and more dominant types in other regions; e.g. the Acavidæ and Achatinidæ in South Africa and Ortman's classical explanation of the mutual exclusiveness of the Freshwater Crayfishes and Crabs. The concomitant expansion of an arm of the Indo-Pacific Ocean continually further between India and Australia, Africa and Antarctica, and extending eventually between Africa and South America (to form the Atlantic), was shown to have far-reaching consequences in aiding the dispersal of the marine fauna, e.g. the Siluriid Fishes, Galaxias, and the ancestors of the Freshwater Crayfishes. Difficulties in the way of explaining certain features of the fauna of New Zealand, which has been permanently above the sea only since Tertiary times, were shown to be obviated by the new hypothesis.—W. H. **Logeman**: An easily constructed automatic Toepler vacuum pump

Animal Mechanism.

THE presidential address of Sir Charles Sherrington to the British Association at Hull directs our thoughts to problems of the mechanism of vital processes, especially to those of the nervous system. It is evident that the obstacles which we meet with in our progress to better understanding of what happens in those complex systems which we call "living" have greatly occupied the attention of the learned president, and those of us who are struggling on our way will be grateful for his helpful and stimulating outlook. We shall do well to take careful note of his remarks.

The great difficulty which continually presents itself to us is the conception of any physiological process as a whole. We find out, often at the expense of much labour, some isolated facts, but the integration of these facts to explain the complete mechanism remains beyond our powers. Take the case of muscle. We discover that muscular contraction and relaxation are associated with a change from glycogen to lactic acid and back again. But how is the energy of the chemical reaction converted to that of tension, which is the really important matter? It is easy to say that it is through changes in surface tension on longitudinally arranged elements, but we soon meet with further difficulties. It may be remarked that more work is needed on the electrical properties of surfaces and especially as to the effect of electric charge on the rate of passage of ions through membranes which are themselves charged. The problem in the nervous system shows itself in the form of finding out what happens in the centres between the receipt of an afferent "sensory" impulse and the motor reaction to it. How is the impulse directed into some particular channel and prevented from passing into another? Why does it go sometimes one way, and at other times in another way? What is it that stops it after it has been set going? The president is careful to point out that when the physiologist says "why" he means "how," and we must not forget this.

It will be realised that one of the most important and difficult problems, especially suggested in the last of the questions put above, is that of inhibition. Is it possible to account for all the phenomena on the basis of difference in rate, refractory period and decrement as affecting the transmission of a nervous impulse? The article on "Spinal Reflexes" by Prof. Alex. Forbes in *Physiological Reviews* gives us a very valuable account of what can be done in this way. On the other hand, is there evidence for the existence of something essentially different between excitation and inhibition? When a nervous impulse arrives at a muscle cell or a neurone in activity, is there some

structure in which it ends that causes it to stop abruptly the process going on? In other words, are there two opposite processes of excitation and inhibition, similar in nature but opposite in sign? We come across the old problem of duality, of some philosophical interest. The question as to the existence of positive and negative electricity, as in the nucleus and electrons of an atom, is a cognate one, and we are reminded of the frequent physiological opposition between anions and cations.

With respect to the hope or probability of further progress in the explanation of vital processes, Sir Charles Sherrington directs attention to the justification that what has already been done gives us in believing that "further application of physics and chemistry will furnish a competent key" to many mechanisms. Although we may not be able to construct such mechanisms ourselves, we may understand the principles on which they work, somewhat as a man may be able to explain how an electro-motor works, notwithstanding that he may not have the skill to make one. There are, however, other things, more particularly concerned with growth and development, which we, as yet, are a long way from comprehending. What it is that makes a living creature a united whole and "how the mind is connected with its bodily place" belong to these. The question is asked, "Can we suppose a unified entity which is part mechanism and part not?"

The latter part of the address is devoted to some important relations of the physiology of the brain to the doctrines of psychology and sociology. We must not leave out of consideration the combination of individuals into social organisms, "new in the history of the world." Man must feel that to rebel against this great supra-individual process "would be to sink lower rather than to continue his own evolution upward."

There are many apposite points brought out in the discussion on the "mental" functions of the brain. We know that the integrity of certain parts of the brain is essential for mental activity, while what we call the lower levels are non-mental. Since we step from one world to another, as it were, when we pass from a nerve impulse to a psychical event, we might expect that there would be some striking change of structure when we cross the boundary between the non-mental and the mental regions of the brain. But we find the "same old structural elements." "The structural interconnexions are richer, but that is merely a quantitative change." Another difficult problem is the position of psychical events in the energy balance-sheet of the body. Do they take their place in obeying the first law of energetics? But the whole of this discussion must be read in the address itself to be properly appreciated.

The United States Chemical Foundation.

EARLY in July last, President Harding instructed the Alien Property Custodian of the United States to demand the return of all patents, trade marks, etc., which had been sold to the Chemical Foundation, on the ground that "the sale was made at so nearly a nominal sum that there is reason to believe that this government has not faithfully observed the trust which was implied in the seizure of this property." The birth of the Foundation was the subject of much abuse in Germany, and now a resolution of the third German-American National Conference, with Mr. G. S. Viereck as chairman of the resolutions committee, declares that "we greet with satisfaction the first steps of the administration to correct the iniquities committed by the custodian of alien enemy property." Meanwhile, the consternation produced among chemists of the United States by the President's action will be readily understood.

The Chemical Foundation was established in 1919, and purchased 4000 patents from the Alien Property Custodian for a sum of 250,000 dollars. It is a privately managed enterprise, with well-known men of high character as voting trustees, and the president, Mr. Garvan, is not salaried. The Foundation was generally commended at the time of its inception, and its affairs appear to have been conducted on altruistic principles and without profit. Non-exclusive licences have been granted in order to break monopolies and to benefit consumers; licences to the Government have been free, and on others the royalties have been low. To illustrate the beneficial effect of this policy, it has been stated that under the German monopoly the cost of salvarsan was 4·50 dollars per dose to the physician, and 2·50 dollars per dose in quantity to the Government, whereas now the price has fallen to 1·50 dollars and about 30 cents, respectively.

A reasonable conclusion to draw from such evidence is that although the original price paid by the Foundation for the patents may have been "nearly a nominal sum" if regarded as a monopoly price, it was nevertheless a fair competitive price. Action is being taken by the American Chemical Society, which represents some 15,000 men and women working in educational institutions, research laboratories, and industrial plants, who regard the Chemical Foundation as the nucleus of organic chemical industry in the United States. The society, through a committee which does not include dye-makers or chemical manufacturers, is seeking a conference with President Harding for the purpose of presenting information which it believes he cannot have received before adopting such revolutionary procedure.

Galton's Centenary.

Francis Galton, 1822–1922: A Centenary Appreciation. By Karl Pearson. (Department of Applied Statistics, University College, London. Questions of the Day and of the Fray, No. 11.) Pp. 23. (London: Cambridge University Press, 1922.) 2s. net.

PROF. KARL PEARSON does not think that this generation is likely to do justice to the part Sir Francis Galton played in the spread of human knowledge and in its application to the future of the human race. His own appreciation he would have others share, and he whips them with scorpions as an inducement. As he says, "the time is hardly suited to impressing on the majority of men a conviction of the futility of most of their aims, of the depths of their ignorance of what makes for progress, and of the unsatisfying nature of their present pleasures."

The welcome appreciation begins with an account of Victorian science, the science of Darwin, Lyell, Hooker, Faraday, and other giants, which, he says, little men belittle—for it is impossible to appreciate Galton unless we bear in mind that he was the product of the Victorian epoch. Endowed with a fine inheritance, Francis Galton had the advantage of broad training and wide experience, very different from the early specialisation of to-day; "he had far more mathematics and physics than nine biologists out of ten, and more biology than nineteen mathematicians out of twenty, and more acquaintance with diseases and anomalies than forty-nine out of fifty biologists and mathematicians together." Darwin awoke him from "the torpor of tribal dogmas," and turned his widely interested mind to the problems of evolution. Along both observational and experimental lines, he began to study sweet-peas, moths, and man. "In his notebook on the sweet-pea experiments occur the first correlation table, the first regression curve, and the first numerical measure of the intensity of heredity, *i.e.* that between mother and daughter plant." From Mendel's peas has arisen the greater part of modern genetics; from Galton's there sprang the correlational calculus, solidly founded in "Natural Inheritance" published in 1889.

Darwin had suggested, contrary to his usual method of keeping to observed facts, the hypothesis of "pangenesis," that hereditary particles or gemmules given off from the various structures of the body are concentrated in the reproductive cells, and influence the development of these into new individuals. Galton suggested an experimental test, transfusing the blood of different kinds of rabbits to see if the offspring were influenced. The results showed that the transfusion had no effect on the offspring, and Galton tacitly discarded pangenesis. But continued reflection led him, as it also led Weismann, to the idea of germinal continuity. We believe that the idea of parent and child being successive representatives of the same "stirp" or germ-plasm had occurred, more or less clearly, to two or three other biologists before either Galton or Weismann; but Prof. Karl Pearson seems to find something "little" in directing attention to historical anticipations. There is no doubt, however, that "Galton's idea of the 'stirp,' better known under the name given to it by its later German propounder [we should say, 'independent discoverer'], the 'continuity of the germ-plasm,' has played a very large part in modern theories of heredity." It has indeed enabled biologists to understand for the first time clearly why like *must* tend to beget like.

From the fundamental idea of germinal continuity there arose in Galton's mind two broad principles, (1) that bodily modifications, or "acquired characters" in the technical sense, are not likely to be transmitted; and (2) that the differences in the characters of the offspring produced by a difference of stirp are immensely more important than those which can be produced by differences of environment. From his study of identical and non-identical twins he concluded that "nature" is indefinitely stronger than "nurture." We confess to sympathy with what Prof. Pearson calls the platitude that "nature" and "nurture" are inseparably correlated as two essential components of one resultant. Moreover, we feel sure that Galton was naturalist enough to know that improvements in "nurture" may determine the meshes of the sieve in relation to which germinal fluctuations and mutations—better and worse changes in "nature"—are sifted.

It is plain, however, that pondering over the relative evolutionary values of "nature" and "nurture," led Galton to the question which dominated the rest of his life: what evolution may mean for man. What Pasteur was along one line, Galton was along another, a pioneer in the biological control of life. Can man's constitution—in modern phraseology, his gametic composition—be improved, by mating best with best, and fit with fit, and by refraining from sowing tares with wheat? Or may we hope to effect some progress by amelioration of "nurture"—environmental, nutritional, and functional? For improved "nurture" may prompt, for all we know, progressive germinal variations; may determine the survival or elimination of variations; may, in viviparous organisms, count for much in the ante-natal life, and may, in mankind, have an almost hereditary influence on the amelioration of the social *milieu*. Galton's view was that the improvement of the human *breed* was the promiseful line

of evolution, but we cannot think of him as failing to appreciate the manifoldness and the subtlety of nurtural influences, both on the individual and on the race.

Prof. Pearson gives us in his masterly appreciation a useful tonic. "The laws of evolution are open to our study, let us once understand them, and man can elevate man as he has developed his domestic animals—such was the gospel of Galton" Here we are all agreed, Galton was a great man of science and also a social reformer; and it is a satisfaction to all men of goodwill that he continues to live with such vigour in the Laboratory which he founded. The appreciation has as its frontispiece a beautiful sketch of Sir Francis Galton in 1910, in his "still unexhausted exuberant youth."

Modern Dietetics.

Vitamins and the Choice of Food. By Violet G. Plimmer and Prof. R. H. A. Plimmer. Pp. xii + 164. (London: Longmans, Green and Co., 1922.) 7s. 6d. net.

THE old view that a diet was satisfactory, provided that it contained a certain amount of protein and had a sufficient calorie value, has, as is now well known, been modified in two very essential particulars. The quality of the protein is of the first importance; it must supply the particular amino-acids required by the consumer, and must supply them in the proper amount. Further, there must be present the vitamins, the exact nature and function of which are still unknown, but which are essential for growth and health.

It is to these two aspects of the subject that the present work is chiefly devoted, the authors having set themselves the task of producing an account suitable for the general reader. In this they have been on the whole successful, although occasionally the superabundance of facts renders the matter difficult of assimilation. After an introduction dealing with the general principles of dietetics, the subject of the vitamins and their discovery is developed on orthodox lines. The important question of quality of protein, led up to and illustrated by an account of pellagra, is then treated, and the book concludes with two very interesting chapters on the effect of partial deficiencies in the food and errors in selection of food. In an appendix are given a table of distribution of the vitamins in food-stuffs and lists of food-stuffs rich in each of the three vitamins, followed by a very useful series of notes on food-stuffs, from which a good idea of the efficiency of a diet can be easily and rapidly obtained. The book is well produced and contains a number of interesting illustrations.

It is an inevitable consequence of the rapid progress which is being made in this branch of dietetics that the position with respect to some of the matters dealt with has changed considerably since the book was printed. This is notably the case with regard to rickets, the very recent work of McCollum and of Korenchevsky on experimental rickets in rats, and the remarkable discovery of the preventive and healing effect of sunlight on this disease, having come too late for inclusion. Similarly, the large part played by atmospheric oxidation in the inactivation of the antiscorbutic vitamin is not made clear.

The gospel preached by the authors is the orthodox one that safety is to be found in fresh natural food-stuffs, and it is wisely pointed out that instinct, often believed to be a guide to the choice of food, is no longer so under the conditions of modern civilisation. White bread, for example, almost universally preferred in this country, is far inferior in vitamine potency to wholemeal or "germ" bread, and no instinctive need is felt for green vegetables and salads. The choice of food must be guided by knowledge, and it is pointed out that the distribution of food within the family is often conducted on quite erroneous principles.

> "Children are supposed to be sufficiently nourished if they have bread and jam and plenty of puddings with little meat or butter. It is unfortunately the custom to give to the father or wage earner the best food, whereas his requirements for heavy manual work are actually better satisfied by the high energy value of bread, jam, and margarine. The child needs the wherewithal to grow, that is protein and vitamins in addition to calories."

It is in the provision of fresh vegetables to supplement the staple diet of bread, margarine, and meat, all very poor in vitamins, that the chief value of the allotment movement lies (as pointed out by Drummond), and it is to be hoped that the great extension of this system which was called forth by the necessities of the war will be maintained and still further increased in the scarcely less strenuous times of peace.

Even natural food-stuffs, however, are by no means constant in their content of vitamins. Little is known as yet of the cause of the variations in vegetable products at different periods of growth and under diverse conditions, but that wide variations occur has been definitely proved. In products derived from animals this variation is still more marked, and the authors rightly lay stress on this fact, pointing out that the potency of materials such as animal fats, and above all milk, depends upon the diet of the animal from which it is derived.

"The milk of cows at grass contains more A-factor than the milk of the same cows on their winter food . . . At certain times of the year a child receiving fresh whole cow's milk may for this reason only be getting a small amount of this vitamin . . . Breast-feeding is no protection against rickets if the mother's food is poor in A-factor."

The provision of fresh natural food stuffs, although greatly to be desired, is a matter of much difficulty, especially in large towns, and is often impossible when military expeditions or explorations in barren regions have to be undertaken. Then the problem of preserving food stuffs without destruction of their vitamins becomes of great interest and importance. The chief methods for the prolonged preservation of food are canning or bottling and drying, and a considerable amount of investigation has already been directed to the question how far these methods of treatment affect the vitamins. Up to the present, however, sufficient attention has not been paid to the influence of oxidation in these processes. The results so far obtained vary very much with the nature of the material employed. Thus vegetables on drying, as a rule, undergo a considerable loss of antiscorbutic power, that of cabbage being reduced by drying in the air at 37° to about 5-10 per cent. of the value of the fresh material. (The authors are not quite clear on this point, the somewhat misleading statement being made that "cabbage has been successfully dried by a special process devised by Holst and Frohlich.") Retention of antiscorbutic power by material in the dry state seems to depend on the complete absence of moisture.

Heat sterilisation as applied in bottling and canning processes affects the antiscorbutic more than the other two vitamins, but the influence of oxidation is very great. However, it has been found in practice that a material originally rich in the vitamin, like the tomato, will withstand the commercial process and yield a powerfully active product, canned tomatoes having been successfully used for the prevention of scurvy. Again lemon-juice in presence of the natural oil of the rind retains its potency for long periods. There seems, indeed, to the writer, to be no insuperable difficulty in the way of the provision of preserved foods containing at all events a large proportion of their original vitaminic potency. Much further investigation on this subject, on strictly quantitative lines, is, however, required, and at present each case must be separately examined, no generalisation being as yet justified. It is, moreover, not beyond the bounds of probability that some method will before long be found of enriching cheap edible oils so that they may supply vitamin A as well as energy at a reasonable cost.

Interesting problems are suggested by almost every page of this book, and it cannot fail to be of great value in disseminating sound doctrine on a subject concerning which there is now widespread ignorance.

Germany and English Chemical Industry.

Englands Handelskrieg und die chemische Industrie. Von Prof. Dr. A. Hesse und Prof. Dr. H. Grossmann. Band 1. Pp. iv + 304. Band 2. Neue Folge. *England, Frankreich, Amerika.* Pp. iv + 344. Band 3. *Dokumente uber die Kali-, Stickstoff- und Superphosphat-Industrie.* Herausgegeben von A. Hesse, H. Grossmann, und W. A. Roth. Pp. iv + 204. (Stuttgart: F. Enke, 1915-1919.) 98 marks.

THIS work consists of a series of translations of lectures, speeches, and articles by English, French, American, Russian, and Italian chemists, and by certain publicists like Lord Moulton, and by public bodies as the British Science Guild, which appeared at the outbreak of the Great War, or immediately prior to it. In addition, a number of utterances by public men and others, of more or less importance, have been culled from newspapers and the periodical press to support what is the apparent purpose of the publication, namely, to insinuate that the real motive which impelled England to participate in the war was her distrust and jealousy of Germany's industrial pre-eminence, especially in the chemical arts, and her consciousness that she was losing the world's markets owing to Germany's greater technical skill and scientific knowledge, and her better business organisation and financial methods. This idea is implied in the title of the work. It has been sedulously propagated in Germany that the real author of the war was England, and that it was solely to her diplomacy that the catastrophe was brought about: an explanation, and it may be added an exculpation, which doubtless commends itself to the soul of the Teuton.

There is, of course, no necessity to refute an implication which is notoriously at variance with the facts, and is certainly not held by ordinarily well-informed people, even in Germany. But it is characteristic of German mentality that it should have been seriously entertained even in 1915, when the first volume of this work was issued, and that persons of the position of its editors should have been found to support it.

The translations of the English lectures and addresses, most of which have appeared in the recognised journals dealing with applied chemistry, seem to have been well rendered, although exception may occasionally be taken to the comments and explanatory notes which the editors have appended. But it is more

L 1

particularly to the tone and purport of the introductory matter which prefaces the several volumes, and for which they are solely responsible, that exception is chiefly to be taken.

At the same time there is an element of unconscious humour about the whole production. In view of the hardihood with which they reproduce, for the benefit of German readers, the many strictures on German commercial methods with which they have been visited, one is tempted to suggest that their knowledge of our national literature might have disposed the editors to prefix as a motto on their title-page the lines:

O wad some power the giftie gie us
To see oursels as others see us!
It wad frae monie a blunder free us
And foolish notion.

But possibly these strictures are really considered by them as implying a compliment to what they regard as their business acumen, but what other people are apt to characterise as "sliminess."

Railway Electric Traction.

Railway Electric Traction. By F. W. Carter. Pp. viii + 412. (London: E. Arnold and Co., 1922.) 25s. net.

THE problems of electric traction on railways deserve special study at the present time. In the past, electrification has been adopted, as a rule, only when abnormal difficulties, such as the existence of a long tunnel, busy urban traffic, very steep gradients, or a very high price for fuel, had to be overcome. It will be remembered that, largely as the result of a tunnel accident attributed to an accumulation of noxious gases, the New York authorities insisted that practically all lines entering the city should be electrified. The underground railways of London, the Simplon tunnel, and the Belt line tunnel of the Baltimore and Ohio Railway, electrified so long ago as 1895, are further examples. The Norfolk and Western Railroad, a heavy goods line, was electrified because of its long and steep gradients. For the same reason the Chicago Milwaukee and St. Paul Railway, which crosses the Rocky Mountains, had to electrify several of its sections. The development of electric railways in Switzerland, in Sweden, in Bavaria, and in Italy is mainly due to the high price of fuel in these countries.

It does not follow, however, that electric traction should be used only when special difficulties have to be overcome. When steam operation is a commercial success, the justification of electrical operation must be that it provides increased transport facilities with no increase in the rates. With steam operation individual power generation is employed, whereas with electrical operation the power is developed in bulk at central stations. In the electrical system a breakdown at a vital point may stop traffic over a wide area, and to obviate this risk a large amount of capital has to be expended in stand-by plant. In several cases, however, it is more advantageous for the railway to purchase its power from a "bulk supply" station. A disadvantage of a steam locomotive is that it consumes fuel so long as it is in commission; whether it is inside or outside the shed, and whether it is at rest or in motion. Tube-cleaning, oiling, and overhauling also occupy a considerable time. The electric locomotive, on the other hand, takes power only when running, and the time spent in inspection, overhauling, and cleaning is insignificant. Experience shows that for a given service the number of electric locomotives required is less than half the number of steam locomotives, but to make the comparison fair it has to be remembered that each electric locomotive must be debited with its share of the working costs of the central station.

The advisory committee of the Ministry of Transport has decided in favour of the direct current system, with a line pressure of 1500 volts, but multiples or submultiples of this pressure may be used. The French, Belgian, and Netherlands governments have come to a like decision. There are, however, thoughtful advocates of single-phase and polyphase systems. Luckily the difference in cost of the various electric systems does not exceed about one, or at the most two, per cent. of the total cost of running the railway. Although from many points of view standardisation of systems is desirable, yet we think that at the present time the carrying out of the single phase system adopted by the London and Brighton Railway and the direct current system of the North Eastern Railway will be for the benefit of the country.

In the volume under notice the author gives an excellent discussion of the mechanical and electrical problems which traction engineers have to consider. He points out that the bad riding qualities of a locomotive are due to one or both of two general causes, namely, the constraint of the wheels to follow other courses than those towards which they naturally tend, and the setting up of resonant oscillations under the control of the springs. The phenomena of "nosing" and "rearing" he ascribes to the former cause, and those of "rolling" and "pitching" to the latter.

The book can be recommended to the traction engineer, who will find not only a good account of the most modern practice, but also many original dynamical discussions which have a direct bearing on his everyday work. It will well repay study.

Our Bookshelf.

(1) *Hampshire.* By T. Varley. (Cambridge County Geographies.) Pp. xi+212. (Cambridge: At the University Press, 1922.) 3s. 6d. net.

(2) *Munster.* Pp. xii + 176. (3) *Ulster.* Pp. xii + 186. (The Provinces of Ireland.) Edited by George Fletcher. (Cambridge: At the University Press, 1921.) 6s. 6d. net each.

(4) *A History of the County of Bedford.* (The Victoria History of the Counties of England.) Part 1, *Geology and Palæontology.* Pp. 36. (London: Constable and Co. Issued in parts, 1920.) 3s. 6d. net.

(1) MR. VARLEY'S volume is one of the excellent series of the Cambridge County Geographies. The general plan of the series is followed, successive chapters being devoted to different aspects of the county, relief, geology, hydrography, natural history, climate, people, place-names, occupations, history, architecture, and so forth, concluding with a gazetteer of towns and villages. There are a number of illustrations and coloured orographical and geological maps. The maps include the Isle of Wight, which otherwise is outside the scope of the book, but unfortunately they stop short at the county boundaries. This seems to be a needless curtailment of their usefulness. The volume is an excellent handbook to the county and is full of information, but it certainly would be improved by an index. Two criticisms may be offered, which apply rather to the scheme of the series than to this useful volume in particular. The treatment of England by counties can never be completely satisfactory, as it inevitably cuts across geographical regions. Thus the omission of eastern Wiltshire cuts out part of the Avon valley, while the inclusion of the northern slope of the Hampshire downs includes a fragment of country that would be better treated with Berkshire. The other criticism refers to the use of the term geography, as applicable to the book. Since the series claims to be geographical, there should be more correlation of various distributions than is actually the case in the pages; causal effects are not sufficiently emphasised. This is particularly the case with regard to the distribution of population and the sites of towns.

(2) and (3) These volumes are on much the same plan, but they do not claim to be geographies, although in some respects the two volumes are more geographical than the English one. The coloured maps are not strictly confined to the area under consideration, and the regions treated being large, if not always naturally defined, lend themselves to more satisfactory treatment. There is no gazetteer of towns and villages, but a full index to each volume. The books should find a wide acceptance in giving a trustworthy and impartial account of Ireland.

(4) The well-known Victoria History is now published in parts, each of which may be purchased separately. It is thus possible to obtain a full but concise memoir on the geology, botany, zoology, occupations, etc., of each of the counties, furnished with coloured maps by Bartholomew. The separate parts for some thirty counties are now on sale. Many readers whose interests do not embrace all aspects of county lore will be grateful to the publishers for this means of making accessible the scholarly articles of the Victoria History.

A Synopsis of the Accipitres (Diurnal Birds of Prey). Part 1 (Vultur to Accipiter). Part 2 (Erythrotriorchis to Lophoaetus). Part 3 (Herpetotheres to Pernis). By H. Kirke Swann. Second edition, revised and corrected throughout. Pp. 1-63, 65-122, 123-178. (London: Wheldon and Wesley, Ltd.) 6s. each part.

THE work issued in 1920 as "A Synoptical List of the Accipitres" has now reappeared in an enlarged and revised form under the above title. The new edition affords original descriptions of a number of new sub-species, includes others which have appeared elsewhere; gives the type-species of each genus; the type localities of each species; and, alas, further changes in nomenclature. The Synopsis will be most appreciated by those who have some knowledge on the subject, for the extreme brevity of its descriptions of the ordinal, generic, specific, and sub-specific characters will not be of much help to the general student. The diagnostic characters of the species are restricted to adult plumages, and leave untouched the immature stages, which are the most difficult of all. The treatment of the geographical range of the various forms is also very brief.

A monograph of the Accipitres is an admitted desideratum, and as Mr. Kirke Swann has evidently devoted much attention to their study, perhaps he will supply the want. Such a treatise dealing with the plumages, distribution and life-histories would be much appreciated, especially as the birds of this order are among the most attractive and interesting of the class Aves.

Life-histories of North American Gulls and Terns. Order Longipennes. By Arthur Cleveland Bent. Bulletin No. 113. (Smithsonian Institution, United States National Museum.)

THIS is the second instalment of an important work on the life-histories of North American birds, the first of which, dealing with the order Pygopodes, has already been noticed in NATURE.

In this volume Mr. Bent, who possesses an intimate personal knowledge of the birds of the order Longipennes, gained during extensive travels as well as in the laboratory, has been fortunate in securing the co-operation of a number of field-naturalists; and their combined experiences, supplemented by important published matter, has resulted in a remarkable series of life-histories of the fifty species of gulls and terns which are members of the Nearctic avifauna.

Under the description of each of the birds there are sections devoted to habits, nesting, eggs, young, plumages, food, behaviour, and distribution. All of these are treated in an interesting manner, and are made further attractive by a series of beautiful coloured plates, 38 in number, depicting the eggs of each species, while a second series of 77 plates, from photographs, illustrate breeding colonies, sitting-birds, nests, chicks in down, half-feathered young, and haunts. The work, apart from the absence of coloured figures of the adult birds themselves, is wonderfully complete, and is a valuable contribution to ornithological literature.

The Individual and the Community. By R. E. Roper. Pp. 224. (London: G. Allen and Unwin, Ltd., 1922.) 8s. 6d. net.

MR. ROPER has produced a thoughtful and, in many respects, a stimulating book. He is a whole-hearted evolutionist, who regards the failure of post-war reconstruction as arising from the fact that our statesmen have resorted to outworn precedents while neglecting the teachings of evolution. There is, he maintains, a wilful confusion of State and community. A community he defines as "an association of two or more human beings for common (though not of necessity identical or similar) purpose or advantage in their evolution." Immediately the common purpose ceases, the community also ceases. Taking each of the principal States of Europe in turn, Mr. Roper shows that, owing to the division which has been made and is perpetuated by the financial-governing class between themselves and the working-governed class, none of them constitutes a community in his sense. The imposition of the will of one section of society upon another which is involved in our modern system of government by the majority is therefore fundamentally wrong. The difficulty is old, and if in practice we have made no very essential advance beyond the compromise expressed in Rousseau's distinction between *le volonté de tous* and *le volonté général*, it is an advantage that it should be kept before our minds by the clear vision of writers such as Mr. Roper.

Metric System for Engineers. By C. B. Clapham. (Directly-Useful Technical Series.) Pp. xii+181+3 charts. (London: Chapman and Hall, Ltd., 1921.) 12s. 6d net.

THE author's justification for his book is that "even among those who use the millimetre in drawing-office or workshop there are probably few who feel confident in calculating with metric units," and his object is to explain the metric system and to state in full how to convert from the English units to metric units, and *vice versa*. Incidentally there is given an excellent account of the vernier and other devices used by engineers for accurate measurement. The book should be of great use in industrial life: the conversion tables are very exhaustive

A brief survey is offered of the controversy which has been raging for so long round the question whether the metric system should or should not be introduced compulsorily in this country. It is claimed that this survey is not a piece of propaganda work in favour of the change, but the arguments given *pro* and *con* do much to support the view, that a good deal of the opposition to the enforced use of the metric system in England is attributable to mere conservative objection to change. Mr. Clapham's book is itself one of the best arguments in favour of the change—why should the Englishman be condemned to waste so much time and energy in making conversions and in looking up tables of equivalents? S. B.

Wild Bush Tribes of Tropical Africa. By G. C. Claridge. Pp. 314. (London: Seeley, Service and Co., Ltd., 1922.) 21s. net.

MR. CLARIDGE'S "Bush Tribes" are the Ba-Congo of Northern Angola, and the country the inhabitants of which he describes stretches from the Congo on the north to St. Paul de Loanda in the south, and from the Kwilu and Kwangu rivers in the east to the Atlantic. He writes of the native with sympathy, but, for the most part, despises his customs: he rarely fails to stigmatise them as "degrading," "disgusting," or worse when he has an opportunity. Notwithstanding this drawback, as it must seem to those who wish to study native custom impartially, the author has given a full and careful account of Ba-Congo culture, and his collection of folk-lore is both interesting and useful. The most important part of his book deals with fetishism, and, in particular, with the N'Kamba fetish of the women, which controls their most important function, that of child-bearing. The men are rigorously excluded from the rites of this fetish. A "Death and Resurrection" secret society, which effects "cures" by death and rebirth, is described from information supplied by a native, but here unfortunately the author's prejudice colours the narrative to such an extent that considerable knowledge of similar societies is required to disentangle the facts.

Readable School Physics. By J. A. Cochrane. Pp. xi+131. (London: G. Bell and Sons, Ltd., 1922.) 2s. 4d.

A TEACHER who loves his subject will find matter of interest for his pupils even in its most prosaic parts. "This book," writes Mr. Cochrane in an interesting Preface, "is an attempt to humanise Elementary Physics without popularising it." We are of opinion that in this task the author has achieved very considerable success. Theory has been given the main prominence. Experiments have not been described unless to elucidate principles. References to the makers of scientific history are frequent, and are reinforced by a number of interesting plates which include portraits of Newton, Pascal, Boyle, Galileo, and Joseph Black. The pupil's own experience is brought into connexion with physical principles as often as possible. Part 1, which might have been called Mechanics instead of Hydrostatics since it includes chapters on volume, weight, and density (not to mention surveying), occupies about two-thirds of the book, the remainder being devoted to what is certainly a "readable" account of the elementary principles of heat.

Ions, Electrons, and Ionising Radiations. By Dr. J. A. Crowther. Third Edition. Pp. xii+292+ii pls. (London: Edward Arnold and Co., 1922.) 12s. 6d. net.

THE first edition of Dr. Crowther's useful manual has already received notice in these columns (August 12 1920, p. 740.). The fact that a third edition has been called for so soon is sufficient evidence that the book has been appreciated. The material has been thoroughly revised and the various tables of constants brought into accord with the best data obtainable. Siegbahn's work on X-ray spectra and Aston's work on positive rays receive notice, and an account is given of Sir Ernest Rutherford's recent work on the problems of atomic structure and of Bohr's theory. We have no hesitation in recommending this volume to readers desiring a systematic account of the latest developments in physics.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

The British Association.

THE Association is to consider whether it will once more adventure into the outer regions of the Empire. That such transgress is desirable I am satisfied and so stated most definitely in the lecture I gave in 1915, at the Royal Institution, on our Australian excursion. In the interest of the younger scientific generation and of our Empire, it is of the utmost importance that we should roam over the world and discover its amenities—but the effort must be wholehearted, whenever it be made. The one failure of our Australian expedition was the insufficient support of the younger men.

It is a question whether, at the present time, when the cost of travel is so high, it will be desirable to attempt a new expedition—the chance that it will be well supported by the young men is not great. The Society of Chemical Industry could carry only a very small party last year to Canada. Therefore, the choice of a region that shall not be too distant is desirable, if the decision be to travel.

Properly speaking, the Association should go further westward, to British Columbia, north of the C.P.R., to visualise its potentialities and gain some idea of its conditions. To recommence the cycle at a middle point such as Toronto seems undesirable, at present. Montreal is the natural and would be the proper point of redepature and discovery. It has also the advantage that it is the centre of the only region on the American continent where freedom still prevails and men are thought to be capable of taking care of themselves. It is the duty of science to protest and erect some barrier against the advancing wave of spurious puritanism which so affects Americans and now so threatens the freedom of mankind. The recent all but successful attempt to ban Darwinism in every shape and form is sufficient proof of what may happen.

HENRY E. ARMSTRONG.

Bohr and Langmuir Atoms.

CHEMISTS feel a difficulty in explaining molecular combination in terms of electrical attraction between the apparently revolving electrons which seem to compose the peripheral parts of an atom; and they naturally prefer a more static arrangement. Indeed, it is not easy to explain the stability of molecules in terms of any kind of purely electrical attraction between the atoms composing them; and yet, ever since Faraday, there has been an instinctive feeling that electrical attraction and chemical affinity are one and the same.

The facts of spectroscopy seem to insist on a system of revolving electric charges, while the facts of chemical combination seem to demand forces which can be treated statically; so it has been suggested that internal electrons are responsible for the radiation, while external electrons control the chemical forces. But the stability of chemical compounds can scarcely depend on loosely held external electrons, which, moreover, ought to be revolving just as much though not so fast as the inner ones.

May not a reconciliation be found by abandoning the idea of electrical attraction between atoms as the major chemical force, and substituting for it the interlacement of the magnetic fields which inevitably accompany rapidly revolving electric charges. The orbital motion of the electrons responsible for chemical affinity, so far from constituting a difficulty, gives us a clue; for in every magnet electrons are rapidly revolving, and yet magnetic force is static. The clinging together of nails or needles near a magnet is all due to revolving electrons. Working with magnetised steel spheres, tetrahedra, and other shapes, some one with the ingenuity of Dr. Langmuir or Prof. Bragg might succeed in building up structures or models of adequate chemical significance.

The difficulty about substituting a magnetic field for an electric one, as accounting for the facts of chemical affinity, is no doubt the double polarity. But, on the other hand, this inevitable feature gives greater scope as well as greater complexity, and may ultimately be found to be an advantage; in fact, I am beginning to think that the constitution of bodies cannot be explained without it. The phenomena which long ago suggested "normal- and contra-valence" would fall into line. The stability of chemical combination would be all that could be desired, and the electrons in each atom would be peacefully engaged in giving their spectroscopic evidence (so well interpreted by the genius of Prof. Bohr), unharassed in their movements and perturbations by having to associate themselves with any electric field other than that of their own nucleus. Then magnetic linkages would be a sort of unconscious extra.

The undoubted phenomenon of ionisation would have to be developed independently, along with other known facts about gross positive and negative electric charges, but in the formation of stable chemical molecules we should not have to appeal to ionic charge. Moreover, certain molecular groupings, held together by magnetic forces, might be found readily susceptible to ionisation, especially when subject to bombardment, or when packed close together in a liquid.

I do not suppose that magnetic attraction as the equivalent of chemical affinity is any new idea, but I suggest that it has been inadequately developed, and that it seems capable of effecting a reconciliation between the extraordinarily ingenious schemes—apparently opposed, and yet both containing elements of truth—of which the names at the head of this letter may be regarded as principal types.

OLIVER LODGE.

The Acoustics of Enclosed Spaces.

SINCE writing the letter published in NATURE of August 19, p. 247, my attention has been directed to a paper on "Sound Proof Partitions" by Prof. R. F. Watson (University of Illinois Bulletin for March 1922). The paper contains a valuable experimental investigation on one aspect of the subject, but much remains to be done.

I take this opportunity of correcting an error which seriously affects the numerical results I gave for the sound transmitted through walls. In applying the optical equations, I forgot for the moment that the intensity of reflection in the case of sound does not only depend on the refractive index but also on the relative densities of the two bodies concerned. Even if the refractive indices were equal, so that the sound would proceed in the same direction, there would still be a powerful reflection if the densities were very unequal. In the equation I gave, $1-\mu^2$ should be replaced by $\alpha-\mu^2\alpha^{-1}$, where α is the ratio of the densities. When sound passes from air to a solid body the second term is in general negligible, and

the transmitted intensity depends almost entirely on the ratio of the densities If we take the case of a partition of wood having a density half that of water, calculation then shows that at normal incidence about 4 per cent of the sound is transmitted if the thickness be 1 cm Reducing the thickness to 2 mm, the intensity of the transmitted sound increases to 50 per cent, and rises to 80 per cent if the thickness is only 1 mm

What I desired to emphasise in my previous letter is that the diminution in the sound transmitted with increasing thickness is not necessarily due to any absorption, but is explained by the effect of the reflection at the second surface which, when the thickness is small compared with the wave-length, neutralises the reflection at the first surface This does not appear to be sufficiently appreciated, and some of the conclusions drawn in Prof Watson's paper require correction accordingly The effect of the second surface is also of importance when total reflection ought to take place according to the usual formulæ at the first surface With a thickness less than a wave-length, part of the sound is transmitted. This case has been treated by Lord Rayleigh ("Collected Works," vol vi p 71)

ARTHUR SCHUSTER

The Annelids of Iceland and the Faroes.

THIS is a subject about which very little has hitherto been known In discussing the part which white ants play in the economy of nature Prof Henry Drummond compared them with earthworms He referred to Darwin, and said that in "Vegetable Mould" a reference was made to the existence of earthworms in Iceland I cannot find any such allusion It is true that a few worms have been recorded for Iceland and one for the Faroes I am fortunately in the position to add somewhat to our knowledge My son, Dr J Newton Friend, having recently returned from an expedition in those islands, I have had the privilege of examining his collection of annelids The following are the results:

The common earthworm (*Lumbricus terrestris*, L) flourishes in Iceland I examined twenty-three specimens, twenty of which were perfectly adult Not one of them differed in any particular from the type as found in England I hoped to find spermatophores, but in this matter disappointment was experienced The specimens were collected near Reikjavik at the beginning of August, and were just in the right condition for laying their cocoons

The red earthworm (*L rubellus*, Hoffm) was also found Though adult it was smaller than our English specimens usually are, and the dorsal surface was of a darker brown colour I have often found similar specimens, however, in the British Isles, so that they are in no sense to be looked upon as a variety

The purple worm (*L purpureus*, Eisen = *L castaneus*, Sav) has already been recorded, alike for Iceland and the Faroes Thus each of the three common species of European Lumbrici is now known to be a denizen of Iceland To these may be added two species of the genus Dendrobaena One of these (*D rubida*, Sav) is best known by the variety usually named the gilt-tail, a denizen of ripe manure and decaying leaves The other (*D octoedra*, Sav) although widely distributed geographically, is not a common species in Great Britain Up till the present, then, five species only of the Lumbricidae have been recorded

The shores of Iceland, if they could be worked as Claparede worked the Hebrides, would doubtless yield a variety of forms, especially the red-blooded pot-worms or pachydrilids. None of these, so far as I am aware, has been up till the present placed on record, but *Clitellio arenarius*, O. F. M., well known on our English coasts, is reported for the coasts of Iceland.

I can find no records for the Faroes except the purple worm already noted. It is, therefore, with peculiar pleasure that I am able to add two new members to the list These are both enchytraeids, and were collected in peaty earth near a stream some two miles inland from Thorshaven One of these was a pachydrilid (*Lumbricillus lineatus*, O F. M) I have written fully on the synonymy in the *Irish Naturalist*, and my conclusions are supported by the more recent investigations of the American helminthologist, Welch

The other enchytraeid is of the white-blooded kind (*Mesenchytraeus oligosetosus*, Friend) It was found some time ago among gleanings made in Jersey, and described by me in the *Zoologist* I have more recently found a striking variety of this worm, or an allied species, near Birmingham The Faroes material agreed with the Jersey The worm is about a third of an inch in length, and belongs to the group which has enlarged setae on the segments which contain the spermathecae. It may also be noted that I found one of the commoner opalines parasitic in the Faroese enchytraeids Our list therefore stands thus *Mesenchytraeus oligosetosus*, Faroe Is, *Lumbricillus lineatus*, Faroes; *Clitellio arenarius*, Iceland, *Dendrobaena rubida*, Iceland, *Dendrobaena octoedra*, Iceland, *Lumbricus purpureus*, Faroes and Iceland, *Lumbricus rubellus*, Iceland, *Lumbricus terrestris*, Iceland

Addendum (Aug 16) —A further investigation with pocket lens has resulted in some interesting additions to the foregoing list

Achaeta minima Southern, only 1 mm in length, but agreeing exactly in all particulars with the material from Ireland The intestine contained peaty soil with a number of diatoms

Marionina (Chamaedrilus) sphagnetorum (Vejd) — Very slender, but true to type White (colourless) blood. I stated my reasons in these columns some time ago for transferring this species to the genus Chamaedrilus

Dorylaimus obtusicaudatus Bastian A fine female nematode, about $2\frac{1}{2}$ mm long All from the Faroes

HILDERIC FRIEND

Cathay, Solihull

On the Reality of Nerve-Energy.

THE expression "nerve-energy" is widely used both by non-technical writers and by medical and physiological authors as well

What the former mean by it is of no particular moment; but in medical and physiological literature it should connote something quite definite, if indeed the existence of nerve-energy is admitted at all There seems a doubt whether its existence is to be admitted in a formal sense, for although certain physiologists use the expression nerve-energy as a convenient term, the thing itself is not discussed in their text-books, nor does it find a place in the indexes

If nerve-energy has no place in the scheme of things vital as conceived by modern physiologists, then the term ought not to be used by them just because it is occasionally a very useful one When they do use it, it means no more than "innervation."

The subject is full of difficulties, one of which is our having to reckon with the use of the still vaguer

terms "vital energy" or "biotic energy." To narrow the problem, let us in the meantime exclude "vital" energy altogether, since, *as an expression*, it must include nerve-energy.

Now it is well known that one or two writers have, years ago stated their belief in the reality of nerve-energy, of such are Sir William Hale White and Prof. Macdougall, then of Oxford, now of Harvard. Dr. Hale White in 1886 (*Lancet*, July 24) suggested the term "neurorheuma," and Macdougall in 1903 "neurine" for just the same thing as is understood by "nerve-energy." These terms were introduced to supply suitable technical terms (in place of the popular "nerve-energy") to designate a reality among the other forms of energy. Macdougall's term "neurine" has not been more readily adopted, because he associated it with a theory of inhibition which has occasioned much criticism.

Adopting for the moment Hale White's "neurorheuma," it means "flow in a nerve." But flow of what? Surely of nerve-energy. Some physiologists would not say so: they would reply—flow of nerve-impulses. Naturally, for nerve-impulses are the only things which do or can flow in nerves. Now nerve-impulses are real, and as they are the only things which flow in nerves, and nerve-energy is in nerves, then nerve-energy is but a synonym for nerve-impulses. This is exactly what Dr. White intended, for he insisted that nerve-energy was but one kind of energy amid several other kinds, heat, light, electricity, etc.

In itself nerve-energy is clearly *sui generis*, because the neurons (nerve cells and fibres) to which it is exclusively related are themselves histologically *sui generis*.

Now no one would teach that the nerve-fibres are the sources of the impulses they transmit; it is the cell-bodies which alone can be dynamogenic. The problem of the transmutation of nerve-energy into some other form of energy must in the meantime be left unattacked.

If energy there be, the cells are the only sources transmitting it to the fibres. Nerve-energy must be capable of existing both in the potential and kinetic states. Such indeed seems to be the truth, for it may be regarded as potential in the cells and kinetic in the fibres. But in the last analysis, what is this potential energy but that liberated by the metabolism of the nerve-cell, one aspect of the oxidations and reductions going on there? No physiologist would deny the reality of the existence of this fundamentally chemical energy of the neurone, but what is it if it is not nerve-energy?

Nerve-impulses (nerve-energy) being *sui generis* must make their measurement very difficult, if not impossible, except in terms of some other form of energy.

Now the most measurable thing which nerve-impulses do is to produce electric current. Why is the E.M.F. of this current not a sufficiently good measure of nerve-energy? It is sometimes assumed that we can measure the intensity of nerve-impulses by the muscular, cardiac, glandular, or other "work" which they evoke. It is true that feeble innervation will give rise to feeble muscular effort, violent to violent. But caution is necessary in drawing deductions as to the potential of the feeble and violent innervations respectively.

The feeble muscular effort may be feeble because only a few muscular fibres are excited, the strong because many; and all the while the actual E.M.F. of the nerve-impulses which excited the feeble effort may be the same as that of those which excited the violent.

The violent neural antecedent may be one that, involving many nerve-cells in the commotion, "fires off" many muscle-fibres, while the feeble neural antecedent involves few; but the E.M.F. of the nerve-impulses in both cases may be the same. The work of Keith Lucas would lead us to this conclusion.

But all this does not affect the doctrine of the *reality* of nerve-energy. Nerve-energy is real although its measurement is difficult and may be impossible. We believed in the reality of animal heat, electricity, and light long before we were able to measure these by calorimeters, galvanometers, and photometers. Nerve-impulses impinging on a muscle stir it to activity or quell it to inactivity, so that they must be at least as real as the muscular energy excited or quelled respectively. Similarly nerve-impulses impinging on a nerve-cell cause it to transmute its potential nerve-energy into nerve-impulses.

Contrary to what the phrase would imply, Muller's "specific nerve-energy" does not throw any light on our problem. The phrase is antiquated though it embodies an important truth. What Muller had in mind was the oneness of the central result with the many forms of the peripheral stimulation.

Unless nerve-energy is a reality, neurasthenia becomes meaningless. Now although the term "neurasthenia" may not connote a definite clinical entity, yet fatigue of the nervous system both in its acute and chronic forms is a fact. From *a priori* considerations alone there must be fatigue of neural origin as of any other. The partial solution of the granules of Nissl has been asserted to be the histological counterpart or basis of fatigue of neuroplasm, but whether or not this be correct, a state of functional disability must be capable of being induced in neurones. Surely fatigue means diminution of some sort of energy: muscular fatigue is a reality, why not neural? Physiologists doubt the "fatigueability" of nerve-fibres which are but conductors, but no neurologist doubts the "fatigueability" of nerve-cells. This must, in other words, be nothing else than the diminution of the potential and quantity of the energy of neurones. All the following writers have used the expression "nerve-energy" or "nerve-force": the late Dr. Hughlings Jackson, the late Dr. Clouston, the late Sir William Osler, the late Dr. Weir Mitchell, the late Dr. Frederick Taylor; and of living writers, Sir William Bayliss, Profs. Halliburton, Howell, and Starling, and Sir Frederick Mott.

In closing let me make one or two suggestions as to how nerve-energy might be measured.

1. The increase of conductance in the skin under the influence of descending nerve-impulses as measured in the psycho-galvanic phenomenon (Waller, Golla). Surely the magnitude of this is causally related to that of the antecedent nerve-energy liberated? Even if this be proved to be a glandular phenomenon, we have the essentials of quantitative estimation in it.

2. Measure the E.M.F. of the current of action, say, in the cortical visual centre as the result of feeble and of strong retinal stimulation respectively.

3. Estimate the pressures or other stimuli necessary to suppress certain reflexigenous tendencies.

D. FRASER HARRIS.

Dalhousie University, Halifax, N.S.

Noctiluca as an Enemy of the Oyster.

IN view of the serious problems which have of late been engaging the attention of oyster culturists, involving as they do the whole future of the industry, and in connexion with which a considerable amount of scientific investigation has been carried out, the following preliminary note of observations made by

Mr. H. P. Sherwood, assistant naturalist to the Ministry, may be of interest.

Experiments in oyster culture in tanks are being carried out by the Ministry at Conway on a large scale, and have been in progress for several years. In order to throw light on the frequent failure of spat settlement under natural conditions, and the remarkable success which has almost uniformly attended the breeding experiments in the Conway tanks, special attention has been directed to the identification of enemies of the embryo oyster. Some six weeks ago large numbers of *Noctiluca miliaris* were noted in the Conway estuary, which has since contained this organism in varying quantity. Laboratory experiments were carried out, and Mr Sherwood noted a remarkable and rapid diminution in the numbers of oyster embryos placed in aquaria in the presence of Noctiluca. He afterwards found that many of the Noctilucas contained from one to four oyster embryos. The embryos were seen at the outset in, or in close proximity to, the peristome and mouth, later becoming scattered through the substance of the Noctiluca, enclosed in distinct food vacuoles.

Mr Sherwood has made a long series of confirmatory observations, and the actual ingestion of the embryos has now been repeatedly observed, including the transference of the embryo to parts remote from the mouth.

Many exceedingly interesting observations with regard to the mechanism of ingestion, etc., have been made, but a full description would be out of place in a short communication. It may, however, be noted that the tentacle of Noctiluca appears to take no active part in the process of ingestion. The behaviour of the embryos suggests that their movements, and therefore power of escape, are inhibited after contact with the oral groove, either by entanglement of the cilia with mucus, or by actual paralysis induced by the action of some "stinging" mechanism. Further investigation is required, however, before any definite deductions can be drawn.

When it is considered that Noctiluca often occurs in the sea in enormous numbers, and that each Noctiluca can dispose of at least as many as four oyster embryos at a time, the importance of this observation will be apparent. I am informed that great quantities of Noctiluca have recently been observed in the vicinity of the oyster beds at Orford.

Another observation recently made by Mr. Sherwood, in connexion with the disappearance of oyster spat, is of interest. Not only has he found oyster embryos in the stomachs of adult oysters, but also has found the stomach of a "black sick" oyster, taken from a tank in which there was no free-swimming spat, crammed with embryos in the same stage of development as those found in the gills of the parent oyster. It would thus appear that the oyster is not only a cannibal, but also even devours its own young before extrusion.

The very interesting observations made by Dr. J. H. Orton (NATURE, August 5, p. 178) on the ingestion of oyster embryos by *Aurelia aurita* throw further important light on the question of failure of oyster spat fall.

R. W. DODGSON.

Ministry of Agriculture and Fisheries,
Fisheries Experiment Station,
Castle Bank, Conway, August 18.

Defoliation of Oaks.

IN view of the deplorable effect of repeated defoliation of oaks by the larvæ of *Tortrix viridana*, as noted by Mr. E. W. Swanton in NATURE for August 19, p. 250, it may be useful to remind planters that there are two distinct races of British oak (*Quercus robur*, Linn.), to which some botanists have assigned specific rank as *Q. pedunculata*, Ehrh., and *Q. sessiliflora*, Salisb. The latter, known in the vernacular as the durmast oak, prevails as an *indigenous* growth in the western and north-western parts of Great Britain, throughout the English Lake District, and in Ireland. In eastern England and Scotland and in midland and southern England the pedunculate oak predominates, but not exclusively, for I have found that the old trees in Merevale Park, Warwickshire, survivors of the ancient Forest of Arden, are durmast, while such oaks as have been planted there are pedunculate.

The timber of these two varieties (or species) are of equal quality, the durmast being of straighter growth than the other; but there is an important and well-marked difference in their relative susceptibility to the ravages of Tortrix. The Hon. Gerald Lascelles, late deputy surveyor of the New Forest, directed my attention to this many years ago. "I have seen," he said, "a sessile oak standing out in brilliant foliage when every other oak in the wood around was as bare of leaf as in winter."

Subsequent careful observation in all parts of the country has fully confirmed Mr Lascelles's statement. Unfortunately, the durmast forms and ripens acorns far less frequently than the pedunculate oak; hence the difficulty of obtaining durmast seedlings and plants from nurserymen, and the vast preponderance of the pedunculate oak in British and Irish plantations.

HERBERT MAXWELL.

Black Coral.

PROF HICKSON, in his interesting article on Black Coral (NATURE, August 12, p. 217), alludes to the remains of Noah's Ark as quoted by Josephus from Berosus and others. It is said in Josephus (*loc. cit.*) that "the remains of the timber were a great while preserved." There is in the Monastery at Etchmiadzin a small piece of Noah's Ark carefully framed. It was given by an angel to a monk named James, who had wandered on Ararat in search of it for seven years (see J. B. Telfer, "The Crimea, etc.," 1876, p. 250). So far as I could see, when I examined it in 1898, it was neither wood nor fossil wood, but asbestos. This does not render improbable the occurrence of bitumen in the neighbourhood, but why does Prof. Hickson assume that the amulets were bracelets? In default of evidence that Noah utilised the Ark for dredging, there does not seem any reason to connect him with black coral.

F. A. BATHER.

Metallic Coloration of Chrysalids.

IN NATURE of November 3, 1921 (vol. 108, p. 302), a letter of mine appeared on the "Metallic Coloration of Chrysalids." During the present year I have had the opportunity of observing some very fine examples of the chrysalids of *R. urticæ*, in which the gilding extended over the whole surface. It may be of interest, as bearing on the origin of the colour, to note that when the gilding was very gently scraped, the gold first turned to green and then to blue. In the course of a few days the scraped area assumed the same appearance as the whole chrysalid does after the butterfly has emerged, namely, a yellowish white.

A. MALLOCK.

9 Baring Crescent, Exeter, Aug. 24.

The British Association at Hull.

THE British Association meetings are now in progress, and notwithstanding a slight difficulty which threatened to arise in obtaining rooms for the unusual influx of visitors, this has been removed and things are running smoothly. The Local Committee has endeavoured to improve the appearance of the city as much as possible by elaborate signposts, and metal signs on the electric standards, indicating the positions of the various meeting rooms and sectional lecture halls. Thus the usual appearance of a town visited by the British Association being transformed into a bill-posting station, has been avoided. Similarly, in the Reception Room and in other places, are gaily coloured artistic banners and signs in profusion, in addition to which the Parks Committee has made the rooms gay with plants and blooms.

Various corporations and public bodies in the east of Yorkshire have risen to the occasion, and, with the co-operation of the North-Eastern Railway Company, an elaborate system of special trains has been arranged to convey the members to different parts of this attractive county.

The Corporation of Scarborough is entertaining four hundred members; the Yorkshire Philosophical Society is entertaining the same number of members in the York Museum, where an official welcome will be given by the Lord Mayor; the Corporation of Harrogate is also entertaining four hundred members; Bridlington is entertaining 250, and Beverley 100 These are in addition to arrangements made in Hull itself, which include a river trip to Spurn Point in the s.s. *Brocklesby*, kindly lent by the Great Central Railway Company, on which occasion the members will be entertained by the Local Committee.

There is also a garden party in Hymers College grounds (the old Botanical Gardens), where the members will be entertained by the Hull Literary and Philosophical Society, the Local Committee, and the Governors of the College.

Various firms in Hull and district (Messrs. Reckitt and Sons, the Humber Portland Cement Company, Earle's Cement Company, The British Oil and Cake Mills, Needler's Confectionery Works, the Olympia Oil Mill, Selby, and the Hull Fishing Vessel Owners' Association) are showing parties round their respective places and providing refreshment, etc.

On account of the wealth of suitable lecture and committee rooms, the work of the various sections is running smoothly, and the new Guildhall with its fine reception room, banqueting hall, etc., makes admirable headquarters, while the reception room is in easy access of the various offices placed at the disposal of the general and local officers of the association.

An experiment has been tried in the provision of an artistic numbered badge for each member, for the purpose of identification, and also for admission to the various functions of the association in place of, or in addition to, the familiar membership ticket, which, like many innovations for the Hull meeting, has been made a convenient size.

The Hull Tramways Committee has granted free tram-rides to the wearers of badges, to the great convenience of the visitors. T. S.

Report of the Council.

A number of important matters is referred to in the report of the council presented to the meeting of the general committee on September 6. Sir Ernest Rutherford was nominated by the council as president of the Association for the meeting to be held at Liverpool next year.

During the year covered by the report, the Association received from Sir Charles Parsons the generous gift of 10,000*l*. War Stock for general purposes and also a legacy of 450*l*. from the late Mr. T. W. Backhouse. A very welcome gift was one of 75*l*. from Mrs. Sidney Brown to form "the John Perry's Guest Fund" for use by the general treasurer in case of emergency connected with guests of the Association. There is frequent need for financial help such as a fund of this kind may supply, and it is to be hoped that other benefactors will be forthcoming to increase the modest amount now available for this purpose. Certain it is that no more appropriate memorial to the late treasurer of the Association, Prof John Perry, could be established than such a fund would afford. On account of the expanding activities of the Association, professional men who are not members are often invited to give addresses or read papers to one or other of the sections, but under present conditions sectional secretaries have no power to pay even out-of-pocket expenses to such men or offer hospitality to them The least the Association should do in such cases is to pay railway fares and entertain the special visitors as guests.

Provision of a similar kind is made by the establishment of the "British Association Exhibitions" now offered to students not above the standing of B.Sc., nominated by the senate of each of twenty universities and university colleges, and covering the railway fares of such students and their membership if not already regular members. The Local Executive Committee at Hull has kindly supplemented this aid by an offer of financial support and hospitality for such nominees. What is wanted now is to give power to each organising committee of the sections to offer like facilities to two or three leading workers in particular fields to attend meetings for the purpose of expressing their views on aspects of science seen more distinctly from outside the scientific world than within it.

The council has made some important recommendations with regard to the Conference of Delegates and the Corresponding Societies Committee. It has been agreed that the conference at Hull should consider, in the first place, what steps should be taken to induce local societies to group themselves round local (*i.e.* district) sub-centres for the interchange of information and for the more economical publication of the results of research.

The Corresponding Societies Committee is to prepare a general survey of local scientific societies, including information as to existing federations and local unions.

Mr. W. Whitaker has been nominated as president of the Conference at the Hull Meeting.

The following new members of council are nominated: Rt. Hon. Lord Bledisloe, Dr. W. E. Hoyle, and Mr. A. G. Tansley, leaving two vacancies to be filled by the general committee without nomination by the council.

Some Aspects of Animal Mechanism.[1]

By Sir C. S. SHERRINGTON, G.B.E., Sc.D., D.Sc., LL.D., Pres.R.S., President of the Association.

IT is sometimes said that science lives too much in itself, but once a year it tries to remove that reproach. The British Association meeting is that annual occasion, with its opportunity of talking in wider gatherings about scientific questions and findings. Often the answers are tentative. Commonly questions most difficult are those that can be quite briefly put. Thus, "Is the living organism a machine?" "Is life the running of a mechanism?" The answer cannot certainly be as short as the question. But let us, in the hour before us, examine some of the points it raises.

Of course for us the problem is not the "why" of the living organism but the "how" of its working. If we put before ourselves some aspects of this working we may judge some at least of the contents of the question. It might be thought that the problem is presented at its simplest in the simplest forms of life. Yet it is in certain aspects more seizable in complex animals than it is in simpler forms.

Our own body is full of exquisite mechanism. Many exemplifications could be chosen. There is the mechanism by which the general complex internal medium, the blood, is kept relatively constant in its chemical reaction, despite the variety of the food replenishing it and the fluctuating draft from and input into it from various organs and tissues. In this mechanism the kidney cells and the lung cells form two of the main sub-mechanisms. One part of the latter is the delicate mechanism linking the condition of the air at the bottom of the lungs with that particular part of the nervous system which manages the ventilation of the lungs. On that ventilation depends the proper respiratory condition of the blood. The nervous centre which manages the rhythmic breathing of the chest is so responsive to the respiratory state of the blood supplied to itself that, as shown by Drs. Haldane and Priestley some years ago, the very slightest increase in the partial pressure of carbon dioxide at the bottom of the lungs at once suitably increases the ventilation of the chest. Dovetailed in with this mechanism is yet another working for adjustment in the same direction. As the lung is stretched by each inbreath the respiratory condition of the nervous centre, already attuned to the respiratory quality of the air in the lungs, sets the degree to which inspiration shall fill them ere there ensue the opposite movement of outbreath. All this regulation, although the nervous system takes part in it, is a mechanism outside our consciousness. Part of it is operated chemically; part of it is reflex reaction to a stimulus of mechanical kind, though as such unperceived. The example taken has been nervous mechanism. If, in the short time at our disposal, we confine our examples to the nervous system, we shall have the advantage that in one respect that system presents our problem possibly at its fullest.

To turn therefore to another example, mainly nervous. Muscles execute our movements; they also maintain our postures. This postural action of muscles is produced by nerve-centres which form a system more or less their own. One posture of great importance thus maintained is that of standing, the erect posture. This involves due co-operation of many separate muscles in many parts. Even in the absence of those portions of the brain to which consciousness is adjunct, the lower nerve-centres successfully bring about and maintain the co-operation of muscles which results in the erect posture; for example, the animal in this condition, if set on its feet, stands. It stands reflexly; more than that, it adjusts its standing posture to required conditions. If the pose of one of the limbs be shifted a compensatory shift in the other limbs is induced, so that stability is retained. A turn of the creature's neck sidewise and the body and limbs, of themselves, take up a fresh attitude appropriate to the side-turned head. Each particular pose of the neck telegraphs off to the limbs and body a particular posture required from them, and that posture is then maintained so long as the neck posture is maintained. Stoop the creature's neck and the forelimbs bend down as if to seek som[illegible]n the floor. Tilt the muzzle upward and th[illegible]s straighten and the hind limbs crouch as if to [illegible]at something on a shelf. Purely reflex mechanis[illegible]provides all kinds of ordinary postures.

Mere reflex action provides these harmonies o[illegible] posture. The nerve-centres evoke for this purpose in the required muscles a mild, steady contraction, with tension largely independent of the muscle length and little susceptible to fatigue. Nerve-fibres run from muscle to nerve-centre, and by these each change in tension or length of the muscle is reported to [illegible]e activating nerve-centre. They say "tension rising, [illegible] must slacken," or conversely. There are also org[illegible] the stimulation of which changes with any chang[illegible] their relation to the line of gravity. Thus, a pai[illegible] tiny water-filled bags is set one in each side of the s[illegible]ll and in each is a patch of cells endowed with a [illegible]al nerve. Attached to hairlets of these cells is [illegible] tiny crystalline stone the pressure of which acts as [illegible]lus through them to the nerve. The nerve of e[illegible]ty-bag connects, through chains of nerve-ce[illegible] muscles of all the limbs and of one side [illegible] In the ordinary erect posture of the head, [illegible]tion by the two bags right and left is equal, because the two gravity-stones then lie symmetrically. The result, then, is a symmetrical muscular effect on the two sides of the body, namely, the normal erect posture. But the right and left bags are mirror pictures of each other. If the head incline to one side, the resulting slip, microscopic though it be, of the two stones on their nerve-patches makes the stimulation unequal. From that slip there results exactly the right unsymmetrical action of the muscles to give the unsymmetrical pose of limbs and neck required for stability. That is the mechanis[illegible] dealing with limbs and trunk and neck. An addition[illegible] one postures the head itself on the neck. A second pa[illegible] of tiny gravity-bags, in which the stones hang rathe[illegible] than press, are utilised. These, when any cause inclin[illegible] ing the head has passed, bring the head back at once to the normal symmetry of the erect posture. These same bags also manage the posturing of the eyes. The eye contributes to our orientation in space; for example, to perception of the vertical. For this the eyeball, that

[1] Presidential Address delivered at the Hull Meeting of the British Association on Sept. 6.

is the retina, has to be postured normally, and the pair of little gravity-bags in the skull, which serve to restore the head posture, act also on the eyeball muscles. Whichever way the head turns, slopes, or is tilted, they adjust the eyeball's posture compensatingly, so that the retina still looks out upon its world from an approximately normal posture, retaining its old verticals and horizontals. As the head twists to the right the eyeball's visual axis untwists from the right. These reactions of head, eyes and body unconsciously take place when a bird wheels or slants in flight or a pilot stalls or banks his aeroplane; and all this works itself involuntarily as a pure mechanism.

True, in such a glimpse of mechanism what we see mainly is how the machinery starts and what finally comes out of it; of the intermediate elements of the process we know less. Each insight into mechanism reveals more mechanism still to know. Thus, scarcely was the animal's energy balance in its bearing upon food intake shown comfortably to conform with thermodynamics than came evidence of the so-called "vitamins"—evidence showing an unsuspected influence on nutrition by elements of diet taken in quantities so small as to make their mere calorie value quite negligible; thus, for the growing rat, to quote Prof. Harden, a quantity of vitamin A of the order of $\frac{1}{500}$ milligram a day has potent effect. Again, as regards sex determination, the valued discovery of a visible distinction between the nuclear threads of male and female brings the further complexity that, in such cases, sex extends throughout the whole body to every dividing cell. Again, the association of hereditary unit-factors, such as body colour or shape of wing, to visible details in the segmenting nucleus seemed to simplify by epitomising. But further insight tends to trace the inherited unit character not to the chromosome itself, but to balance of action between the chromosome group. As with the atom in this heroic age of physicists, the elementary unit once assumed simple proves, under further analysis, to be itself complex. Analysis opens a vista of further analysis required. Knowledge of muscle contraction has, from the work of Fletcher and Hopkins on to Hill, Hartree, Meyerhof, and others, advanced recently more than in many decades heretofore. The engineer would find it difficult to make a motive machine out of white of egg, some dissolved salts, and thin membrane. Yet this is practically what Nature has done in muscle, and obtained a machine of high mechanical efficiency. Perhaps human ingenuity can learn from it. One feature in the device is alternate development and removal of acidity. The cycle of contraction and relaxation is traced to the production of lactic acid from glycogen and its neutralisation chiefly by alkaline proteins; and physically to an admirably direct transition from chemical to mechanical effect. What new steps of mechanism all this now opens!

But knowledge, while making for complexity, makes also for simplification. There seems promise of simplification of the mechanism of reflex action. Reflex action with surprising nicety calls into play just the appropriate muscles, and adjusts them in time and in the suitable grading of their strength of pull. The moderating as well as the driving of muscles is involved. Also the muscles have to pass from the behest of one stimulus to that of another, even though the former stimulus still persist. For these gradings, coadjustments, restraints, and shifts, various separate kinds of mechanism were assumed to exist in the nerve-centres, although of the nature of such mechanisms little could be said. Their processes were regarded as peculiar to the nerve-centres and different from anything that the simple fibres of nerve-trunks outside the centres can produce. We owe to Lucas and Adrian the demonstration that, without any nerve-centre whatever, an excised nerve-trunk with its muscle attached can be brought to yield, besides conduction of nerve impulses, the grading of them. That is remarkable, because the impulse is not gradable by grading the strength of the stimulus. The energy of the impulse comes not from the stimulus, but from the fibre itself. But Lucas and Adrian have shown, however, that it is gradable in another way. Though the nerve impulse is a very brief affair—it lasts about $\frac{1}{1000}$ second at any one point of the nerve—it leaves behind it in the nerve fibre a short phase during which the fibre cannot develop a second impulse. Then follows rapid but gradual recovery of the strength of impulse obtainable from the fibre. That recovery may swing past normal to super-normal before returning finally to the old resting state. Hence, by appropriately timing the arrival of a second impulse after a first, that second impulse may be extinguished, reduced, increased or transmitted without alteration. This property of grading impulses promises a complete key to reflex action if taken along with one other. The nervous system, including its centres, consists of nothing but chains of cells and fibres. In these chains the junctions of the links appear to be points across which a large impulse can pass, though a weak one will fail. At these points the grading of impulses by the interference process just outlined can lead, therefore, to narrowing or widening their further distribution, much as in a railway system the traffic can be blocked or forwarded, condensed or scattered. Thus the distribution and quantity of the muscular effect can be regulated and shifted not only from one muscle to another, but in one and the same muscle it can be graded by adding to or subtracting from the number of fibres activated within that muscle. As pointed out by Prof. Alexander Forbes, it may be, therefore, that the nerve impulse is the one and only reaction throughout the whole nervous system, central and peripheral,—trains of impulses colliding and over-running as they travel along the conductive network. In this may lie the secret of the co-ordination of reflexes. The nerve-centre seems nothing more than a meeting-place of nerve-fibres, its properties but those of impulses in combination. Fuller knowledge of the mechanism of the nervous impulse, many of the physical properties of which are now known, a reaction which can be studied in the simplest units of the nervous system, thus leads to a view of nervous function throughout the system much simpler than formerly obtained.

Yet for some aspects of nervous mechanism the nerve impulse offers little or no clue. The fibres of nerve-trunks are, perhaps, of all nerve-structures those that are best known. They constitute, for example, the motor nerves of muscle and the sensory nerves of the skin. They establish their ties with muscle and skin during embryonic life and maintain them practi-

cally unaltered throughout the individual's existence, growing no further. If severed, say, by a wound, they die for their whole length between the point of severance and the muscle or skin they go to. Then at once the cut ends of the nerve-fibres start regrowing from the point of severance, although for years they have given no sign of growth. The fibre, so to say, tries to grow out to reach to its old far-distant muscle. There are difficulties in its way. A multitude of non-nervous repair cells growing in the wound spin scar tissue across the new fibre's path. Between these alien cells the new nerve-fibre threads a tortuous way, avoiding and never joining any of them. This obstruction it may take many days to traverse. Then it reaches a region where the sheath-cells of the old dead nerve-fibres lie altered beyond ordinary recognition. But the growing fibre recognises them. It joins them and, tunnelling through endless chains of them, arrives finally, after weeks or months, at the wasted muscle-fibres which seem to have been its goal, for it connects with them at once. It pierces their covering membranes and reforms with their substance junctions of characteristic pattern resembling the original that had died weeks or months before. Then its growth ceases, abruptly, as it began, and the wasted muscle recovers and the lost function is restored.

Can we trace the causes of this beneficent yet so unaccountable reaction? How is it that severance can start the nerve re-growing. How does the nerve-fibre find its lost muscle microscopically miles away? What is the mechanism that drives and guides it? Is it a chemotaxis like that of the antherozooid in the botanical experiment drawn towards the focus of the dissolved malic acid? If so, there must be a marvellously arranged play of intricate sequences of chemically attractive and repellent substances dissolved suitably point to point along the tissue. It has recently been stated that the nerve-fibre growing from a nerve-cell in a nutrient field of graded electrical potential grows strictly by the axis of the gradient. Some argue for the existence of such potential gradients in the growing organism. Certainly nerve regeneration seems a return to the original phase of growth, and pieces of adult tissue removed from the body to artificial nutrient media in the laboratory take on vigorous growth. Prof. Champy describes how epithelium that in the body is not growing, when thus removed starts growing. If freed from all fibrous tissue, its cells not only germinate, but, as they do so, lose their adult specialisation. In nerve regeneration the nerve-sheath cells, and to some extent the muscle-cells which have lost their nerve-fibre, lose likewise their specialised form, and regain it only after touch with the nerve-cell has been re-established. So similarly epithelium and its connective tissue cultivated outside the body together both grow and both retain their specialisation. The evidence seems to show that the mutual touch between the several cells of the body is decisive of much in their individual shaping and destiny. The severance of a nerve-fibre is an instance of the dislocation of such a touch. It recalls well-known experiments on the segmenting egg. Destruction of one of the two halves produced by the first segmentation of the egg results in a whole embryo from the remaining half-egg; but if the two blastomeres, though ligated, be left side by side, each then produces a half-embryo. Each half-egg *can* yield a whole embryo but is restrained by the presence of the twin cell to yielding but a half embryo. The nerve severance seems to break a mutual connexion which restrained cell growth and maintained cell differentiation.

It may be said that the nerve-sheath cells degrade because the absence of transmission of nerve impulses leaves their fibre functionless. But they do not degrade in the central nerve-piece, although impulses no longer pass along the afferent fibres. This mechanism of reconstruction seems strangely detached from any direct performance of function. The sprouting nerve-fibres of a motor nerve with impulses for muscular contraction can by misadventure take their way to denervated skin instead of muscle. They find the skin-cells the nerve-fibres of which have been lost, and on these they bud out twigs, as true sensory fibres would do. Then, seemingly satisfied by so doing, they desist from further growth. The sense-cells, too, after this misunion, regain their normal features. But this joining of motor nerve-fibre with sense-cell is functionless, and must be so because the directions of functional conduction of the two are incompatible. Similarly a regenerating skin-nerve led down to muscle makes its union with muscle instead of skin, though the union is a functional misfit, and cannot subserve function. Marvellous though nerve regeneration be its mechanism seems blind. Its vehemence is just as great after amputation, when the parts lost can of course never be re-reached. Its blindness is sadly evident in the suffering caused by the useless nerve-sprouts entangled in the scar of a healing or healed limb-stump.

There is a great difference, however, between the growth of such regeneration and the growth impulse in pieces of tissue isolated from the body and grown in media outside. With pure cultures, in the latter case, Prof. Champy says the growth recalls in several features that of malignant tumours, for example, multiplication of cells unaccompanied by formation of a specialised adult tissue. A piece of kidney cultivated outside the body de-differentiates, to use his term, into a growing mass unorganised for renal function. But with connective-tissue cells added even breast-cancer epithelium will in cultivation grow in glandular form. New ground is being broken in the experimental control of tissue growth. The report of the Imperial Cancer Research Fund mentions that in cultivation outside the body malignant cells present a difficulty that normal cells do not. To the malignant cells the nutrient soil has to be renewed more frequently, because they seem rapidly to make the soil in which they grow poisonous to themselves, though not to normal cells. The following of all clues of difference between the mechanism of malignant growth and of normal is fraught with importance which may be practical as well as theoretical.

The regenerating nerve rebuilds to a plan that spells for future function, but throughout all its steps prior to the time when it actually reaches the muscle or skin, no actual performance of nerve-function can take place. What is constructed is functionally useless until the whole is complete. So similarly with much of the construction of the embryo in the womb for purposes of a different life after emergence from the womb; of the lung for air-breathing after birth; of the reflex contraction in the fœtal child of the eyelids to protect the

eye long before the two eyelids have been separated, let alone eye hurt or even light can reach it; of the butterfly's wing within the chrysalis for future flight. The nervous system in its repair, as in its original growth, shows us a mechanism working through phases of non-functioning preparation in order to forestall and meet a future function. It is a mechanism against the seeming prescience of which is to be set its fallibility and its limitations. The "how" of its working is at present chiefly traceable to us in the steps of its results rather than in comprehension of its intimate reactions; as to its mechanism, perhaps the point of chief import for us here is that those who are closest students of it still regard it as a mechanism. If "to know" be "to know the causes" we must confess to want of knowledge of how its mechanism is contrived.

If we knew the whole "how" of the production of the body from egg to adult, and if we admit that every item of its organic machinery runs on physical and chemical rules as completely as do inorganic systems, will the living animal present no other problematical aspect? The dog, our household friend—do we exhaust its aspects if in assessing its sum-total we omit its mind? A merely reflex pet would give little pleasure even to the fondest of us. True, our acquaintance with other mind than our own can only be by inference. We may even hold that mind as an object of study does not come under the rubric of Natural Science at all. But this Association has its Section of Psychology, and my theme of to-night was chosen partly at the suggestion of a late member of it, Dr. Rivers, the loss of whom we all deplore. As a biologist he viewed mind as a biological factor. Keeping mind and body apart for certain analytic purposes must not allow us to forget their being set together when we assess as a whole even a single animal life.

Taking as manifestations of mind those ordinarily received as such, mind does not seem to attach to life, however complex, where there is no nervous system, nor even where that system, though present, is little developed. Mind becomes more recognisable the more the nerve-system is developed; hence the difficulty of the twilit emergence of mind from no mind, which is repeated even in the individual life history. In the nervous system there is what is termed localisation of function—relegation of different works to the system's different parts. This localisation shows mentality, in the usual acceptation of that term, not distributed broadcast throughout the nervous system, but restricted to certain portions of it; for example, among vertebrates to what is called the forebrain, and in higher vertebrates to the relatively newer parts of that forebrain. Its chief, perhaps its sole, seat is a comparatively modern nervous structure superposed on the non-mental and more ancient other nervous parts. The so-to-say mental portion of the system is placed so that its commerce with the body and the external world occurs only through the archaic non-mental remainder of the system. Simple nerve impulses, their summations and interferences, seem the one uniform office of the nerve-system in its non-mental aspect. To pass from a nerve impulse to a psychical event, a sense-impression, percept, or emotion is, as it were, to step from one world to another and incommensurable one. We might expect, then, that at the places of transition from its non-mental to its mental regions the brain would exhibit some striking change of structure. But it is not so; in the mental parts of the brain there is nothing but the same old structural elements, set end to end, suggesting the one function of the transmission and collision of nerve impulses. The structural inter-connexions are richer, but that is merely a quantitative change.

I do not want, and do not need, to stress our inability at present to deal with mental actions in terms of nervous actions, or *vice versa*. Facing the relation borne in upon us as existent between them, however, may we not gain some further appreciation of it by reminding ourselves even briefly of certain points of contact between the two? Familiar as such points are, I will mention rather than dwell upon them.

One is the so-called expression of the emotions. The mental reaction of an emotion is accompanied by a nervous discharge which is more or less characteristic for each several type of emotion, so that the emotion can be read from its bodily expression. This nervous discharge is involuntary, and can affect organs, such as the heart, which the will cannot reach. Then there is the circumstance that the peculiar ways and tricks of the nervous machinery as revealed to us in the study of mere reflex reactions repeat themselves obviously in the working of the machinery to which mental actions are adjunct. The phenomenon of fatigue is common to both, and imposes similar disabilities on both. Nervous exhaustion and mental exhaustion mingle. Then, as offset against this disability, there exists in both the amenability to habit formation, mere repetition within limits rendering a reaction easier and readier. Then, and akin to this, is the oft-remarked trend in both for a reaction to leave behind itself a trace, an engram, a memory, the reflex engram, and the mental memory.

How should inertia and momentum affect non-material reactions? Quick though nervous reactions are, there is always easily observed delay between delivery of stimulus and appearance of the nervous end effect; and there is always the character that a reaction once set in motion does not cease very promptly. Just the same order of lag and overrun, of want of dead-beat character, is met in sense-reactions. The sensation outlives the light which evoked it, and the stronger the reaction the longer the sensation persists. Similarly the reflex after-discharge persists after the stimulus is withdrawn and subsides more slowly the stronger the reaction. The times in both are of the same order. Again, a reflex act which contracts one muscle commonly relaxes another. Even so, with rise of sensation in one part of the visual field commonly occurs lapse of sensation in another. The stoppage is in both by inhibition, that is to say, active. Then again, two lights of opposite colour falling simultaneously and correspondingly on the two retinæ will, according to their balance, fuse to an intermediate tint or see-saw back and forth between the one tint and the other. Similarly a muscle impelled by two reflexes, one tending to contract it, the other to relax it, will, according to the balance of the reflexes, respond steadily with an intensity which is a compromise between the two, or see-saw rhythmically from extreme to extreme of the two opposite influences.

Reflex acts commonly predispose to their opposites; thus the visual impression of one colour predisposes to

that of its opposite. Again, the *position* of the stimulated sensual point acts on the mind—hence the light seen or the pain felt is referred to some locus in the mind's space-system. Similarly the reflex machinery directs, for example, the limb it moves towards the particular spot stimulated. Such spots in the two processes, mental and non-mental, correspond.

Characteristic of the nervous machinery is its arrangement in what Hughlings Jackson called "levels," the higher levels standing to the lower not only as drivers but also as restrainers. Hence in disease underaction of one sort is accompanied by overaction of another. Thus in the arm affected by a cerebral stroke, besides loss of willed—that is higher level—power in the finger muscles, there is in other muscles involuntary overaction owing to escape of lower centres from control by the higher which have been destroyed. Similarly with the sensory effects; of skin sensations some are painful and some not, for example, touch. The seat of the latter is of higher level, cortical; of the former lower, sub-cortical. When cerebral disease breaks the path between the higher and the underlying level a result is impairment of touch sensation but heightening of pain sensation in the affected part. The sensation of touch, as Dr. Head says, restrains that of pain.

Thus features of nervous working resemble over and over again mental activities. Is it mere metaphor, then, when we speak of mental attitudes as well as bodily? Is it mere analogy to liken the warped attitude of the mind in a psychoneurotic sufferer to the warped attitude of the body constrained by an internal potential pain? Again, some mental events seem spontaneous; in the nervous system some impulses seem generated automatically from within.

It may be said of all these similarities of time-relation and the rest between the ways of the nervous system and such simpler ways of mind as I here venture on, that they exist because the operations of the mental part of the nervous system communicate with the exterior only through the non-mental part as gateway, and that there the features of the nerve-machinery are impressed on the mind's working But that suggestion does not take into account the fact that the higher and more complex the mental process, the longer the time-lag, the more incident the fatigue, the more striking the memory character, and so on.

All this similarity does but render more succinct the old enigma as to the nexus between nerve impulse and mental event. In the proof that the working of the animal mechanism conforms with the first law of thermodynamics is it possible to say that psychical events are evaluated in the balance sheet drawn up? On the other hand, Mr. Barcroft and his fellow-observers in their recent physiological exploration of life on the Andes at 14,200 ft. noted that their arithmetic as well as their muscles were at a disadvantage; the low oxygen pressure militated against both. Indeed, we all know that a few minutes without oxygen, or a few more with chloroform, and the psychical and the nervous events will lapse together. The nexus between the two sets of events is strict, but for comprehension of its nature we still require, it seems, comprehension of the unsolved mystery of the "how" of life itself. A shadowy bridge between them may lie perhaps in the reflection that for the observer himself the physical phenomena he observes are in the last resort psychical.

The practical man has to accept nervous function as a condition for mental function without concerning himself about ignorance of their connexion. We know that with structural derangement or destruction of certain parts of the brain goes mental derangement or defect, while derangement or destruction of other parts of the nervous system is not so accompanied. Decade by decade the connexion between certain mental performances and certain cerebral regions becomes more definite. Certain impairments of ideation as shown by forms of incomprehension of language or of familiar objects can help to diagnose for the surgeon that part of the brain which is being compressed by a tumour, and the tumour gone the mental disabilities pass. Similarly those who, like Prof. Elliot Smith and Sir Arthur Keith, recast the shape of the cerebrum from the cranial remains of prehistoric man, can outline for us something of his mentality from examination of the relative development of the several brain regions, using a true and scientific phrenology.

Could we look quite naively at the question of a seat for the mind within the body we might perhaps suppose it diffused there, not localised in any one particular part at all That it is localised and that its localisation is in the nervous system—can we attach meaning to that fact? The nervous system is that bodily system the special office of which, from its earliest appearance onward throughout evolutionary history, has been more and more to weld together the body's component parts into one consolidated mechanism reacting as a unity to the changeful world about it. More than any other system it has constructed out of a collection of organs an individual of unified act and experience. It represents the acme of accomplishment of the integration of the animal organism. That it is in this system that mind, as we know it, has had its beginning, and with the progressive development of the system has developed step for step, is surely significant. So it is that the portion in this system to which mind transcendently attaches is exactly that where are carried to their highest pitch the nerve-actions which manage the individual as a whole, especially in his reactions to the external world. There, in the brain, the integrating nervous centres are themselves further compounded, inter-connected, and re-combined for unitary functions. The cortex of the forebrain is the main seat of mind. That cortex with its twin halves corresponding to the two side-halves of the body is really a single organ knitting those halves together by a still further knitting together of the nervous system itself. The animal's great integrating system is there still further integrated and this supreme integrator is the seat of all that is most clearly inferable as the animal's mind. As such it has spelt biological success to its possessors. From small beginnings it has become steadily a larger and larger feature of the nervous system, until in adult man the whole remaining portion of the system is relatively dwarfed by it. It is not without significance, perhaps, that in man this organ, the brain cortex, bifid as it is, shows unmistakable asymmetry. Man is a tool-using animal, and tools demand asymmetrical, though attentive and therefore unified, acts. A nervous focus unifying such motor function will, in regard to a laterally bipartite

organ, tend more to one half or the other and in man's cerebrum the preponderance of one-half, namely, the left, over the other may be a sign of unifying function.

It is to the psychologist that we must turn to learn in full the contribution made to the integration of the animal individual by mind. But each of us can recognise, without being a professed psychologist, one achievement in that direction which mental endowment has produced. Made up of myriads of microscopic cell-lives, individually born, feeding and breathing individually within the body, each one of us nevertheless appears to himself a single entity, a unity experiencing and acting as one individual. In a way the more far-reaching and many-sided the reactions of which a mind is capable the more need, as well as the more scope, for their consolidation to one. True, each one of us is in some sense not one self, but a multiple system of selves. Yet how closely those selves are united and integrated to one personality. Even in those extremes of so-called double personality one of their mystifying features is that the individual seems to himself at any one time wholly either this personality or that, never the two commingled. The view that regards hysteria as a mental dissociation illustrates the integrative trend of the total healthy mind. Circumstances can stress in the individual some, perhaps lower, instinctive tendency that conflicts with what may be termed his normal personality. This latter, to master the conflicting trend, can judge it in relation to his main self's general ethical ideals and duties to self and the community. Thus intellectualising it, he can destroy it or consciously subordinate it to some aim in harmony with the rest of his personality. By so doing there is gain in power of will and in personal coherence of the individual. But if the morbid situation be too strong or the mental self too weak, instead of thus assimilating the contentious element the mind may shun and, so to say, endeavour to ignore it. That way lies danger. The discordant factor escaped from the sway of the conscious mind produces stress and strain of the conscious self; hence, to use customary terminology, dissociation of the self sets in, bringing in its train those disabilities, mental or nervous or both, which characterise the sufferer from hysteria. The normal action of the mind is to make up from its components one unified personality. When we remember the manifold complexity of composition of the human individual, can we observe a greater example of solidarity of working of an organism than that presented by the human individual, intent and concentrated, as the phrase goes, upon some higher act of strenuous will? Physiologically the supreme development of the brain, psychologically the mental powers attaching thereto, seem to represent from the biological standpoint the very culmination of the integration of the animal organism.

The mental attributes of the nervous system would be, then, the coping-stone of the construction of the individual. Surveyed in their broad biological aspect, we see them carrying integration even further still. They do not stop at the individual; they proceed beyond the individual; they integrate, from individuals, communities. When we review, so far as we can judge it, the distribution of mind within the range of animal forms, we meet two peaks of its development—one in insect life, the other in the vertebrate, with its acme finally in man. True, in the insect the type of mind is not rational but instinctive, whereas at the height of its vertebrate development reason is there as well as instinct. Yet in both one outcome seems to be the welding of individuals into societies on a scale of organisation otherwise unattained. The greatest social animal is man and the powers that make him so are mental; language, tradition, instinct for the preservation of the community, as well as for the preservation of the individual, reason actuated by emotion and sentiment, and controlling and welding egoistic and altruistic instincts into one broadly harmonious, instinctive-rational behaviour. Just as the organisation of the cell-colony into an animal individual receives its highest contribution from the nervous system, so the further combining of animal individuals into a multi-individual organism, a social community, merging the interests of the individual in the interests of the group, is due to the nervous system's crowning attributes, the mental. That this integration is still in process, still developing, is obvious from the whole course of human pre-history and history. The biological study of it is essentially psychological; it is the scope and ambit of social psychology. Not the least interesting and important form of social psychology is that relatively new one, dealing with the stresses and demands that organised industry makes upon the individual as a unit in the community of our day and with the readjustments it asks from that community.

To resume, then, we may, I think, conclude that in some of its aspects animal life presents to us mechanism the "how" of which, despite many gaps in our knowledge, is fairly explicable Of not a few of the processes of the living body, such as muscular contraction, the circulation of the blood, the respiratory intake and output by the lungs, the nervous impulse and its journeyings, we may fairly feel, from what we know of them already, that further application of physics and chemistry will furnish a competent key We may suppose that in the same sense as we can claim to-day that the principles of a gas-engine or an electro-motor are comprehensible, so will the bodily working in such mechanisms be understood by us, and indeed are largely so already. It may well be possible to understand the principle of a mechanism which we have not the means or skill ourselves to construct; for example, we cannot construct the atoms of a gas-engine

Turning to other aspects of animal mechanism, such as the shaping of the animal body, the conspiring of its structural units to compass later functional ends, the predetermination of specific growth from egg to adult, the predetermined natural term of existence, these, and their intimate mechanism, we are, it seems to me, despite many brilliant inquiries and inquirers, still at a loss to understand. The steps of the results are known, but the springs of action still lie hidden Then again, the "how" of the mind's connexion with its bodily place seems still utterly enigma. Similarity or identity in time-relations and in certain other ways between mental and nervous processes does not enlighten us as to the actual nature of the connexion existing between the two. Advance in biological science does but serve to stress further the strictness of the nexus between them.

Great differences of difficulty therefore confront our

understanding of various aspects of animal life. Yet the living creature is fundamentally a unity. In trying to make the "how" of an animal existence intelligible to our imperfect knowledge we have, for purposes of study, to separate its whole into part-aspects and part-mechanisms, but that separation is artificial. It is as a whole, a single entity, that the animal, or for that matter the plant, has finally and essentially to be envisaged. We cannot really understand one part without the other. Can we suppose a unified entity which is part mechanism and part not? One privilege open to the human intellect is to attempt to comprehend, not leaving out of account any of its properties, the "how" of the living creature as a whole. The problem is ambitious, but its importance and its reward are all the greater if we seize and attempt the full width of its scope. In the biological synthesis of the individual it is concerned with mind. It includes examination of man himself as acting under a biological trend and process which is combining individuals into a multi-individual organisation, a social organism surely new in the history of the world. This biological trend and process is constructing a social organism the cohesion of which depends mainly on a property developed so specifically in man as to be, broadly speaking, his alone, namely, a mind actuated by instincts but instrumented with reason. Man, often Nature's rebel, as Sir Ray Lankester has luminously said, can, viewing this great supra-individual process, shape his course conformably with it even as an individual, feeling that in this case to rebel would be to sink lower rather than to continue his own evolution upward.

Scientific Problems and Progress.

ADDRESSES OF PRESIDENTS OF SECTIONS OF THE BRITISH ASSOCIATION.

THE THEORY OF NUMBERS.

In his presidential address to Section A (Mathematics and Physics), Prof. G. H. Hardy propounded a series of five problems of general interest in the theory of numbers, which are still awaiting solution.

(*a*) *When is a number the sum of two cubes, and what is the number of its representations?* The density of the distribution of such numbers tends to zero as the number tends to infinity, but no simple criterion by which these numbers can be recognised is known. The least number expressible in more than one way as a sum of two cubes is 1729, which is 12^3+1^3 or 10^3+9^3. Four representations of 19×363510^3 are known, and this is apparently the largest number of such forms which has been obtained.

(*b*) *Is every large number the sum of five cubes?* Two numbers, 23 and 239, require nine cubes; there are fifteen numbers requiring eight, and 121 numbers requiring seven, the largest of the latter being 8042. Six-cube numbers probably disappear before reaching 1,000,000, and possibly five-cube numbers also disappear, but in huge numbers, for four-cube numbers persist for ever.

(*c*) *Is $2^{137}-1$ prime?* This problem belongs to the theory of the so-called "perfect" numbers, each of which is the sum of all its divisors including unity. The number 2^n-1 can be prime only when n is prime, and 137 is the least value of n for which the answer is still doubtful. Two other problems connected with the perfect numbers, for which solutions are still sought are: Can a perfect number be odd? and, are there an infinite number of perfect numbers?

(*d*) *Are there infinitely many primes of the form n^2+1?* The general distribution of primes is, in all essentials, solved, but much remains to be done among numbers of special form. The form n^2+1 is the simplest case of the general form $an^2+2bn+c$, and although an approximate formula, which has been well tested, has been obtained for determining the number of primes, there is no immediate prospect of an accurate proof.

(*e*) *Are there infinitely many prime pairs, p, $p+2$?* This is a particular case of the question whether any group of primes recur indefinitely. Apparently all possible groups recur for ever with definite frequency, and so far as the first million numbers are concerned, the proposition has been tested, but there is no rigid proof of its accuracy.

CHEMISTRY OF THE SUGARS.

PRINCIPAL IRVINE spent the first part of his address to Section B (Chemistry) in discussing the new responsibilities which devolve upon scientific chemists who take advantage of the facilities offered by the Department of Scientific and Industrial Research (see NATURE, July 22, p. 131).

The second section of the address was devoted to an account of how investigations on the sugars carried out in the St. Andrews' Laboratories for many years are being developed so as to include the structural problems of the polysaccharides. These compounds are shown to be composed of comparatively simple units, as indicated below.

Cellulose.—α-Cellulose gives a trimethyl derivative as the maximum substitution product, and this in turn yields on hydrolysis only 2-, 3-, 6-trimethyl glucose. The simplest formula for cellulose would thus be an anhydro-di-glucose, each hexose residue being substituted in positions 1 and 5, but, in order to accommodate the yield of cellobiose obtained from cellulose, the molecule for the latter is held to be that of a tri-(1-, 5-anhydroglucose).

Starch.—The methylation of starch gives a product which contains seven methyl groups for every unit of eighteen carbon atoms. These are distributed in such a manner that one glucose residue contains three methyl groups, while two such groups are present in each of the remaining glucose residues. Starch is thus based on an anhydro-trisaccharide to which a structure has been ascribed.

Inulin.—This polysaccharide is known to be composed entirely of γ-fructose residues, and each of these has now been shown to be identical in structure. It is in the meantime premature to say if inulin is derived from the simple unit $C_6H_{10}O_5$ or from the double or triple multiple of this, but in any event the γ-ketose residues are symmetrically disposed.

A close structural relationship has thus been established between (*a*) cellulose and starch, (*b*) starch and lactose, (*c*) inulin and sucrose.

PHYSIOGRAPHY OF THE COAL-SWAMPS.

THE purport of the presidential address delivered by Prof. P. F. Kendall to Section C (Geology) was to show that coal seams are the result of growth and accumulations of peat, *in situ*, and that all the phenomena of the British coal-measures can be explained upon this hypothesis, with the necessary implication of great deltaic swamps.

The English coal-measures consist of fresh-water muds and sands with occasional intercalations of marine sediments of relatively small amount. This theory is in full accord with what is known of modern swamps and deltas. Two types of sandstones occur; one, having the form and arrangement of deltaic sand-banks, is often of wide extent, the other taking the form of meandering river-channels which may cut out an entire seam, producing a "wash out." One such example, in which 90 ft. of normal measures and large areas of coal are replaced, was mentioned.

The splitting of coal-seams is attributed in some cases to contemporary river-erosion, and in others to local sags, drowning the vegetation and interrupting coal growth. Effects of contemporary earthquakes are recognisable in many seams and districts. They take the form of "lurched" margins of wash-outs, casts of sand-fountains, sandstone dykes, "swillies," or trough-like inflexions of seams, and contemporary faults affecting lower and not upper seams. All these effects are of earlier date than the ordinary faulting of the strata.

In discussing the various types of material which constitute coal-seams, stress was laid on the distinction between coal and cannel. The explanation of "coal balls" proposed by Stopes and Watson is accepted with the corollary that the constituent plants must, in some cases, have grown in salt water.

In conclusion attention is directed to the phenomenon of cleat, that is, the system of jointing in coal, the one coal-measure phenomena for which there is no obvious modern parallel. Observation of its direction all over the world and in deposits of all ages, from Carboniferous to Pleistocene, shows an overwhelming preponderance of N.W.-S.E. in the northern hemisphere and N.E.-S.W. in the southern. This seems to be in some way related to the earth's planetary rôle, but data are not yet sufficiently complete to justify the formulation of a theory. Every morsel of coal, even a single leaf of cordaites $\frac{1}{100}$ of an inch in thickness, exhibits a regular cleat in the specified direction. The absence of cleat in anthracite is held to explain the low ash percentage. Jointing, comparable to cleat and agreeing in direction, occurs in some limestones.

THE PROGRESSION OF LIFE IN THE SEA

IN his address to Section D (Zoology) the president, Dr. E. J. Allen, first discussed the theory that life in the world had its origin in the sea, referring to recent work by Baly on the formation of formaldehyde and sugars by the action of light of short wave-length on carbonic acid and water, and to the views expressed by Church on the building up of an autotrophic flagellate from the ions present in sea-water. An account was given of work on the culture of marine diatoms, showing the necessity for the presence of traces of organic matter before healthy growth of plant life took place. The passage from plant to animal nutrition was illustrated by the chrysomonad Pedinella. A similar change in nutrition was described amongst the Dinoflagellates. The line of progression from the flagellates to the metazoa probably proceeded through the cœlenterates, which represent the highest stage attained by the primary plankton or free-swimming animals. Further development took place when the latter established a connexion with the sea-bottom. Many of the bottom-living animals subsequently again adopted the free-swimming habit, and gave rise to the various groups of animals found in the plankton to-day. Fishes were probably evolved in rivers, and developed their swimming powers to resist the action of the current.

The conditions controlling the production of organic food material in the sea were discussed and some account given of the food-chain from the diatom and peridinian to the fish. Recent work by Hjort and Drummond was described, on the production of vitamin by marine plankton diatoms, and the passage of this growth stimulant through their food into the bodies of fishes, where it is found in the oil of the liver and subsequently in the ovary. In conclusion it was urged that for the solution of problems dealing with practical fisheries the life of the sea must be studied as a whole.

HUMAN GEOGRAPHY.

DR. MARION NEWBIGIN's address to Section E (Geography) was on "Human Geography: First Principles and Some Applications." Geographers are agreed that there is a definite human geography, but little attention has been given to the problem as to the precise way in which man's response to environmental conditions differs from that of animals. Since man once ran into a number of species—or even of genera—it is obvious that there was once a time when there was no distinctively human response, when adaptation led to specific differentiation, just as it does among animals. But since all living men now belong to one species, it is clear that this time has passed. Its passing appears to be associated with the fact that growing intelligence meant that the barriers to distribution which limit the movements of animals ceased to function. This in its turn might have meant that human evolution stopped, that man ceased to be adapted to any particular habitat because fitted for all, were it not that the factors of fixation and isolation, so important in the case of the lower organisms, began to act in a new way. With the growth of cultivation, communities became fixed to particular areas, and if the isolation was sufficient to ensure the necessary continuity and protection during the early stages, a communal as distinct from an individual adaptation appeared. The second part of the address dealt with applications of these general principles to the chief foci of civilisation in Europe and the adjacent lands. Thus the causes which promoted the origin, growth, and decay or modification of the successive cultures of the great river valleys, of the Mediterranean seaboard, and of the forest belt of Western Europe were considered, and the peculiar difficulties encountered in establishing stable communities in the steppe lands of Eastern Europe discussed briefly.

RAILWAY PROBLEMS OF AUSTRALIA.

THE presidential address to Section G (Engineering), by Prof. T. Hudson Beare, was on "Railway Problems in Australia." Two great problems have to be faced by the Commonwealth—(1) the unification of the existing railway gauges, and (2) the joining up of the tropical areas of Northern Australia by a system of railways linking up with the railway systems of the southern and eastern areas of the continent.

(1) The first is a problem which has been prominent since 1888; up to the present no satisfactory solution has been found. Various Royal Commissions have inquired into the matter, and the only point which has been definitely settled is that the standard gauge shall be 4 ft. 8½ in. In 1921 a Royal Commission made two proposals—(1) to convert the main railway system connecting the various capitals from Fremantle to Brisbane to a uniform 4 ft. 8½ in. gauge, the length of track being somewhere about 3300 miles, the estimated cost of conversion and of the necessary new lines being 19,000,000*l*., which would be increased to a total of 21,500,000*l* if all the 5 ft. 3 in. lines in Victoria and South Australia were simultaneously converted to 4 ft. 8½ in., (2) to convert the whole Australian railway system to 4 ft. 8½ in.—this the Commission estimated would cost about 57,000,000*l*., but this estimate has not been accepted by the State railway authorities, and the Premier of South Australia at a recent conference stated that he was of opinion that the total cost would not be far short of 100,000,000*l*. sterling. If some mechanical device for overcoming the break-of-gauge difficulties could be evolved, the need for the expenditure of this enormous sum would be postponed to a period when it is to be hoped costs of constructional work would be greatly reduced.

(2) When the Commonwealth took over the Northern Territory from the State of South Australia on January 1, 1911, an agreement was entered into between the Commonwealth and the South Australian Government to the effect that the Commonwealth Government should construct a north-south railway connecting Port Darwin with Adelaide. It was agreed to construct a railway line from a point on the Port Darwin and Pine Creek railway southwards to a point on the northern boundary of South Australia proper, and a railway northward from a point on the Port Augusta and Oodnadatta railway to connect with the other portion of the line at a point on the northern boundary of South Australia proper. Up to the present no definite steps have been taken to carry out this agreement, but the Commonwealth Joint Standing Committee of Public Works last year appointed a sub-committee to investigate the country of this route and to take evidence. The Commonwealth Engineer for Ways and Works submitted two alternative transcontinental routes: (*a*) a direct north-south line with the necessary branches to connect it with the Queensland railways, estimated cost about 16,000,000*l*., and (*b*) the eastern route, estimated cost about 14,300,000*l*, to which must be added an additional sum of about 1,500,000*l*. if the existing 3 ft. 6 in. line from Port Augusta to Oodnadatta was extended to Alice Springs in order to open up the McDonnel Range country for closer settlement. The urgency for a prompt decision in regard to the route of the north-south line is brought out by the fact that at the present time the journey by sea from Brisbane, the nearest State capital, to Darwin takes longer than the sea voyage from Darwin to Singapore or Hong-Kong, a perilous state of things to the Commonwealth in certain contingencies which need not be more emphasised but are obvious to all who are fighting so strongly for the white Australia policy.

THE STUDY OF MAN.

IN his presidential address to Section H (Anthropology) Mr. Harold Peake said that during the last twelve years an anthropological school has arisen, which regards different groups of men as following, not one single path of evolution, but various routes according to their environment. This view has brought the anthropologist more closely into touch with the geographer, who has thereby become more human and less factual, has interested the sociologist and the economist, has infected many classical scholars, and may even wean the historian from a too exclusive study of kings and politicians. Anthropology may be defined as "the study of the origin and evolution of man and his works." As such it must be psychological as well as physical, dynamic rather than static. Nor must it be limited to the study of backward peoples, but extended to such civilised peoples as those of the Far East and Hindustan. We have much information concerning the arts, languages, and official religions of these regions; too little concerning the physical and mental traits of their "masses," their customs and actual beliefs. Such ignorance leads to constant misunderstanding and friction, as, for example, in India, and this can be removed only by giving our rulers there some training in anthropology. The British Schools at Rome and Athens have been of enormous value in establishing friendly relations. Let there be a British School in India, endowed by private benefactors of both races, to act as an anthropological centre from which would radiate a truer understanding of the ideals of both civilisations. The need for similar institutions in the European region is painfully manifest. It is, in fact, the spirit if not the detailed facts of anthropology which seem most likely to lead to that breadth of view and deeper sympathy which humanity requires. We need this not abroad alone; we have in these islands, as the result of successive invasions, various races, each with peculiarities of outlook which still lead to friction. These the anthropologist must study for the sake, not of knowledge only, but also for the sake of peace.

THE EFFICIENCY OF MAN AND THE FACTORS WHICH INFLUENCE IT.

IN his presidential address to Section I (Physiology) Prof. Cathcart, after a brief discussion of the meaning of the term efficiency, in which he differentiated mechanical and industrial efficiency, went on to emphasise the intimate relation which exists between the efficiency of man in the physiological and industrial sense. There was a tendency to lay too much stress on organisation and machinery; to forget the fact that no matter what mechanical improvements were evolved man was always behind the machine, and that, therefore,

physiological laws must be reckoned with as an essential factor in industrialism. Attention was directed to the tremendous annual loss in time due to sickness and disability, and it was pointed out that primarily this wastage could not be charged to man being of unsuitable design for the work he was called upon to perform; on the contrary, the physiological balance of the organism was beautifully designed to meet most varying strains. After reference to the relation of the various systems, respiratory, circulatory, etc., to the maintenance of efficiency, Prof. Cathcart went on to discuss the factors which, in his opinion, play the predominant rôles in the maintenance of maximum efficiency. He believed that there were, at least, four intrinsic factors, *i.e.* factors directly related to muscle movement—(*a*) the rate of the performance of the work, (*b*) the amount of rest offered to or taken by the subject, (*c*) the rhythm with which the work was performed and (*d*) the work habits developed by the worker. He reviewed each of these factors in turn, the influence of load and the type of work (positive and static) was dealt with under the rate of performance, and the formation of conditioned reflexes in connexion with rhythm and habit. The more extrinsic factors, *i.e.* those less directly related to muscle effort, were next discussed, including the influence of the state of nutrition and the nature of the food supplied, of the work environment, and the psychic factor generally, particular reference being made to monotony of occupation and the part played by the temperament of the worker. Other still more extrinsic factors like housing, personal habits, lighting, heating, ventilation, etc., were also mentioned. The general conclusion reached was that although the real over-all efficiency of the worker could not be causally related to any single factor, further scientific investigation along physiological lines, with the mutual co-operation of the employer, employee, and scientific worker would throw much light on this most difficult and vitally important problem.

Transport of Organic Substances in Plants.

The address to Section K (Botany), by Prof. H. H. Dixon, dealt with the transport of organic substances in plants. Organic substances are conveyed upwards in the rising transpiration and root-pressure currents. The transport is probably mainly effected in the tracheæ of the outer layers of the wood. Ringing may block these channels completely or partially by the introduction of air-bubbles and by exudations from injured cells into the lumina and walls of the tracheæ.

The downward transport of these substances from the leaves to the lower parts of the plant is usually assigned to the bast, although there is weighty experimental evidence that living conduits are not essential. Calculation shows that if the bast were used as the conduit a velocity of flow in it of about 50 cm. per hour would be required. In such narrow tubes as the bast is composed of, with frequent cross partitions and colloid contents, this velocity seems quite impossible. These considerations render it highly probable that the tracheæ of the wood are the path for downward transport also. There is ample experimental evidence for downward as well as upward movement of sap in the tracheæ. Tension in the sap determines a flow from any source above or below. Resistance to transverse flow in the wood practically subdivides that tissue into a number of longitudinal filaments of tracheæ connected anatomically at various levels in the plant. Transpiration from the upper end of one filament may thus lead to a downward motion in a neighbouring one.

There is also conclusive evidence for this reversed motion in intact normal plants.

Recent work has shown that the transfer of stimuli from the receptive to the motile regions of plants is effected by the passage of hormones. In several cases it is certain that the hormones are conveyed in the transpiration current. Moreover, the movement is often basipetal. Such a downward flow is clearly available for the conveyance of organic foodstuffs as well as hormones. Local increases in the permeability of leaf-cells will allow solutions of organic substances to pass into the tracheæ. The tension generated in the sap by the transpiration of other leaf-cells will draw this solution downwards in the tracheæ. Experimental evidence for this method of transport is available. The volume-changes of leaves and parts of leaves observed during transpiration are in all probability the result of these changes in permeability, and are directly connected with the supply of organic substance from the leaf-cells to the transpiration-current for downward transport.

Educational and School Science.

Sir Richard Gregory's address as president of Section L (Educational Science) was a statement of the biological basis of education and a plea for broader conceptions of the scope and substance of science teaching in schools. It is the business of education to promote the right adjustment between the developing human organism and its surroundings, and this implies that the nourishment provided at all stages of growth should be not only such as supplies the needs of the moment but also builds up strength to live a full life under the conditions of the times. School instruction in science is not, therefore, intended to prepare for vocations, but to equip pupils for life as it is and as it soon may be. It is as essential for intelligent general reading as it is for everyday practical needs, no education can be complete or liberal without some knowledge of its aims, methods, and results, and no pupil in primary or secondary schools should be deprived of the stimulating lessons it affords. In such schools, however, the science to be taught should be science for all, and not for embryonic engineers, chemists, or even biologists; it should be science as part of a general education—unspecialised, therefore, and without reference to prospective occupation or profession, or direct connexion with possible university courses to follow. There is very present need for the reminder that science is not all measurement, nor is all measurement science. In the great majority of secondary schools science signifies chiefly quantitative work in physics and chemistry—laboratory exercises and lessons based upon them—and rarely is any attempt made to show the pupils what a wonderful world we live in, or what science has done, and is doing, for them in everyday life. By the prevailing obsession in regard

to quantitative work the pupil is made the slave of the machine, and appliances have become encumbrances to the development of the human spirit. In addition to subjects studied experimentally, there should be general science courses covering a wide field. Geography can be made the unifying principle of such instruction. Practically all the subjects of a broad course of general science are of geographical significance, inasmuch as they are concerned with the earth as man's dwelling-place, and are the scene of his activities.

The Royal Observatory, Greenwich.

THE Royal Observatory is situated in Greenwich Park on the edge of a scarp overlooking the Thames. The ground descends sharply to the north and west. On the east (running diagonally across the photograph) is a level avenue leading southwards to

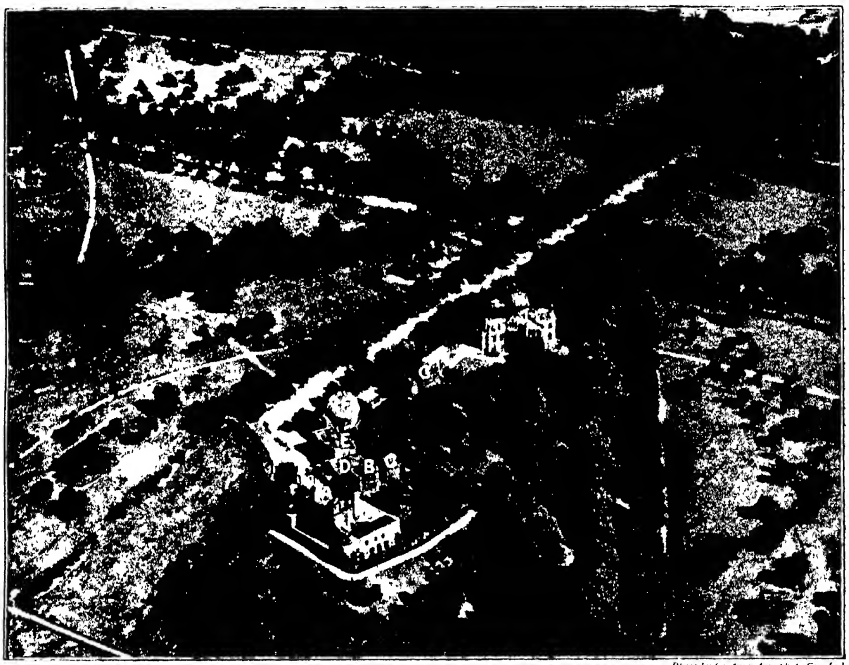

Photo by Central Aerophoto Co., Ltd.

THE ROYAL OBSERVATORY, GREENWICH.

A = ORIGINAL BUILDING. B = ASTROGRAPHIC EQUATORIAL. C = PHOTO HELIOGRAPH. D = TRANSIT CIRCLE. E = SHEEPSHANKS TELESCOPE. F = 28 INCH EQUATORIAL. G = ALTAZIMUTH. H = THOMPSON EQUATORIAL. I = MAGNETIC AND METEOROLOGICAL INSTRUMENTS.

Blackheath. This is joined at an acute angle a little south of the observatory by the avenue from Greenwich, which rises at moderate gradient to the level of the plateau.

The observatory was founded by Charles II. and designed by Wren. The original building, A, is shown surmounted by the time-ball at the north-east corner and anemometers on the north-west and south. The octagon room, so called from its shape, contained in this building was the observatory of Flamsteed, who was commissioned to make observations of the sun, moon, and planets for the assistance of navigators, especially with the view of their utilising predicted positions of the moon among the stars for the determination of longitude at sea. Some of the instruments employed by Flamsteed were in this room, but others were in the open. Under the octagon room are four small rooms where Flamsteed lived. In Maskelyne's and Airy's time additions were made to the house by buildings to the south and west; the part of the Astronomer Royal's official residence looking over the western edge of the scarp is shown prominently in the picture.

To the south of the octagon room are shown two small domes. The first of them, B, covers the astrographic equatorial, a photographic telescope which was erected by Sir William Christie, and has done good service in the photographic mapping of the heavens, the determination of the solar parallax from observa-

tions of the planet Eros, and the determination of photographic magnitudes of stars.

Behind B, at C, is a drum-shaped dome beneath which Airy's altazimuth for observations of the moon was situated. This instrument was taken down in 1911 and a photoheliograph installed, with which the daily photographs of the sun are taken. These with photographs taken at the Cape and supplemented by others from India give a complete daily record of sunspots. They are measured and the results utilised to determine the peculiarities of the sun's rotation and the remarkable 11-year period in sunspots and their connexion with terrestrial magnetism.

To the east of the astrographic equatorial is the transit circle in a building, D, with a gable roof running north and south. This instrument, erected in 1851 by Airy, is on the Greenwich meridian. It has been in constant use for seventy years to determine Greenwich time, and with it regular observations are made for the positions of sun, moon, planets and stars. These observations have contributed very materially to the foundation of the tables and catalogues from which the "Nautical Almanac" is computed. In addition, many other stars have been observed for comparison with earlier observations made by Bradley and others at Greenwich and elsewhere. The small changes in position of the stars among themselves as seen in the sky determined in this way and combined with other data give the sun's motion in space, the average distances of stars, and prove the existence of two streams of stars.

To the left is a building, E, surmounted by a small dome containing the Sheepshanks telescope, used for observations of comets. These buildings also contain office rooms, record rooms, a small laboratory for receiving the wireless time signals from Paris, Bordeaux, Lyons, Nauen, Annapolis, and other stations, and rooms in which chronometers and watches are stored.

The large dome, F, contains the 28-inch equatorial. This large telescope was erected in 1893 on a mounting which had carried the 13-inch Merz telescope, which at the time of its erection in 1860 was the largest telescope in the observatory. The 28-inch refractor is used mainly for the measurement of close double stars.

The care of the chronometers and watches belonging to the Royal Navy is part of the work of the observatory, and the room beneath the large telescope is the main chronometer room; it contains ovens in which chronometers and watches are tested to see that they are correctly compensated. In this room is preserved the beautiful chronometer, made by Harrison, which obtained the Government prize of 20,000*l.*, and a copy of it made by Larcum Kendal which was carried by Capt. Cook on his voyage round the world. On the ground floor is another room for chronometers and refrigerating plant for testing them at low temperatures.

A little to the south is the altazimuth, G. This was erected by Sir William Christie in 1896, and is used to supplement the observations of the moon made with the transit circle. A little south-east is a building used as a store-room, in which the publications of the Greenwich and Cape observatories are housed.

At the extreme south is the new building erected in 1896–1898. It is cruciform, and has on the main floor office rooms, where photographs are measured, calculations made, and observations discussed. The basement consists of libraries and a workshop. Three of the rooms of the upper floor are used for storing records and photographs, the fourth is used for photographic work, such as reproduction of the Franklin Adams Charts. The central part of the building is surmounted by the Thompson equatorial under a 36-ft. dome, H. This instrument, given by Sir Henry Thompson, consists of two telescopes on the same equatorial mounting. One of these is a 26-inch photographic telescope with a guiding telescope of 13 inches, and the other a 30-inch reflector made by Dr. Common The photographic refractor has been put to many uses, including the observation of satellites and minor planets. It is at present used regularly for the determination of the distances of stars, delicate work which is carried on very successfully in spite of difficulties arising from weather and short summer nights. The reflecting telescope has been used for photographing nebulæ, comets, and faint objects where great light-grasping power is required. With it a very faint and distant satellite of Jupiter was discovered. It is at present employed with a coarse grating to determine the colours of stars, or with a spectroscope to study the distribution of light in stellar spectra.

Only one important instrument is not shown in the photograph. The Cookson telescope, lent by the University of Cambridge and used for observation of small movements of the earth's pole, is in a small wooden hut to the east of the octagon room, and is hidden by that building.

Near the top left-hand corner, I, of the photograph is an enclosure in which are two buildings devoted to magnetic observations. Magnetic instruments had to be moved some distance from the main observatory, owing to the effect of iron in the domes on the magnets. Continuous photographic traces are taken showing the changes of the magnetic elements, controlled by regular observations made by eye. This enclosure also contains a radium collector for the study of atmospheric electricity, and various meteorological instruments.

Colour Vision and Syntony.

By Prof. E. H. BARTON, F.R.S.

THE classic theory of colour vision due to Young and developed by Helmholtz and Maxwell attributes the observed phenomena to three sensations (red, green, and violet), but does not enter into detail as to the type of mechanism involved in their stimulus and response. In the days before the discovery of the electron, it was unlikely that any hypothesis of syntony (or sympathetic vibratory response) should be developed for the eye, because nothing was then known of vibrators capable of such high frequencies as those involved in the visible spectrum But it is now open to us to attempt a syntonic hypothesis of colour vision, since so much more is known as to the constitution of the atom and the behaviour of the electrons. The

fundamental facts which recommend the resonance theory of hearing are the smallness and rapidity of those motions which constitute the external stimulus of audition. But how much stronger is the argument based on the corresponding facts for vision! For in vision we are concerned with the frequencies of light, many millions of millions per second, and with displacements correspondingly minute. Further, we now know that in all receptions for wireless telegraphy there must be the tuning of a sympathetic vibrator before the detection of the excessively minute and rapidly alternating disturbances which constitute the signal.

Thus the question naturally arises, Can a syntonic theory of colour vision prove tenable? To answer this we must review the main facts of the case, put forward a specific hypothesis based upon them, and test it against the facts.

CHIEF FACTS OF COLOUR VISION.—These may be classed under five heads: the spectrum, spurious colour mixtures, true colour mixtures, time phenomena, and colour blindness.

(i.) *The Spectrum* of white light extends over nearly an octave (to borrow the musical term) from red with a wave-length of nearly four-fifths μ to violet of wave-length two-fifths μ. The spectrum has no gaps in it, thus showing that we have continuous vision over the range in question. The colours change gradually all the way along the spectrum, and we have six or seven common names for the chief colours occurring. But Dr. Edridge Green finds that the spectrum can be divided into bands, each seeming monochromatic and each different from its neighbours. The number of these bands varies with the observer, but he finds it may reach from 18 to 27 for those with very sensitive colour vision.

(ii.) *Spurious Colour Mixtures.*—By mixing pigments (in water colour or oils) and by superposing coloured glasses or films we really execute a double subtraction of colour and not a true addition at all. Thus blue and green pigments mixed or blue and green glasses superposed almost always give green. This is because each pigment or glass subtracted (or absorbed) certain colours from the whole spectrum and left certain colours, and that of the colours thus left, green was the only one common to both residues. By the same methods red and green will give a low colour approaching grey, or it may give an absolute black. This last effect is easily obtained by superposing two good films, each of which transmits only a limited portion of the spectrum, with no colour common to both films.

(iii.) *True Colour Mixtures.*—These true additions of colour may be obtained by converging two or more coloured beams of light, by the colour top, or by stippling, weaving, or the various colour processes now used in book illustrations. These true mixtures give results quite different from those of the spurious mixtures and thus throw valuable light on colour vision. Thus blue and yellow do not make green but white or a light pinkish tinge; red and green make yellow; red, green, and violet make white, while red and violet give a colour not found in the spectrum.

(iv.) *Time Phenomena.*—It is known that the full acquisition of a visual sensation is not attained under something of the order of a tenth of a second, and that the vision also persists for a like period after the stimulus is withdrawn, before dying out completely. Again, there are effects of fatigue, so that after gazing for twenty seconds at a red object and then at a white surface, a green image appears of the size and shape of the previous red object which had fatigued the eye for red and thus caused the white to appear deficient in red and so look green.

All the facts of colour vision hitherto enumerated apply to those with normal sight.

(v.) *Colour Blindness.*—Finally there are the facts of colour blindness. Some patients are blind to red, others are blind to green or to two of the three colour sensations, some are blind to all three.

SYNTONIC HYPOTHESIS.—In forming a syntonic hypothesis of vision, in which the initial response of the eye to the stimulus of light is supposed due to the sympathetic vibration of something, we must indicate the number of different vibrators imagined to be present at each element of the retina, also the frequencies and dampings natural to them. Since the tri-colour theory of vision has been so successful in many ways it is natural to try first if three vibrational responders could form the basis of a syntonic theory. Obviously if three responders are to suffice their "resonance" or response curves must replace the sensation curves usually drawn to indicate the degrees to which the three colour sensations are excited by the various spectral colours. These curves are much spread and overlap, so that no portion of the spectrum is left without power to excite one or more of the colour sensations. The response curves of the vibrators now postulated can be equally spread by rightly choosing the damping (or dying away of their free vibrations) natural to the vibrator. For, the greater the damping the flatter is the response curve, the less the damping the more sharply tuned is the response. Thus, by the hypothesis of three strongly damped responding vibrators we can account for the visibility of the continuous spectrum just as easily as by the vaguer hypothesis of three colour sensations. What natural frequencies must be assigned to these vibrators? Probably such as to respond to light of wave-lengths rather less than $0{\cdot}76\mu$, about $0{\cdot}55\mu$, and rather more than $0{\cdot}4\mu$. Or we can think of the matter in musical terms as follows, rather sharper than C♯, about F♯, rather flatter than B, all three to be in the same octave.

The Hypothesis Tested.—We have now to test this postulated set of vibrators against the facts of true addition of colours. This test may be carried out mathematically or by experiments with a simple arrangement or model in which the vibrational responders are crudely imitated by pendulums RGV with paper cones as bobs (Fig. 1). (Any form or type of vibrators will serve equally well, as is shown by mathematical theory.) They hang from a stretched horizontal cord AB which is set in motion by the swings of a heavy pendulum CD, as shown in the accompanying figure. To represent a second light stimulus, simultaneously imparted, a second cord, AE, and pendulum FH are provided; the two cords are connected by a bridge of wood near *v* when both drivers are in action.

By the use of this model it is easy to make the desired tests of the hypothesis. In speaking of it we

may conveniently refer to the heavy pendulums by the names of colours, thus "red," if of the same frequency as the "red" responder *r*R, etc.

Tried in this way we find the simultaneous use of blue and yellow drivers does not give the response appropriate to green but gives white, *i.e.* all the three responders are set in motion. On reference to the diagram it is possible to see why this follows. The blue driver (representing blue light) is intermediate in frequency between the responders G*g* and V*v*, and so excites both. The yellow driver has a frequency between those of R*r* and G*g* and excites both. But the simultaneous drives on the green responder will interfere by being often much out of phase, so the response of the green responder is no more than those of the violet and red, indeed the last-named often preponderates. It should be noted that in the above test the colours used as stimuli were both such as had no appropriate responder postulated.

For red and green the case is different; each has an appropriate responder provided in the hypothesis, and each is affected by the corresponding stimulus when red and green pendulums are used as drivers. But when a yellow driver is used, *i.e.* a pendulum intermediate in frequency between the red and green responders, they are both affected as when the separate red and green drivers were in use. Thus, on the hypothesis under examination, the naked eye would mistake a true addition of red and green for a yellow. And this is just what happens when the experiment is tried.

This is quite different from what occurs in hearing, where two notes like C♯ and F♯ when sounded simultaneously are not mistaken for any single intermediate note. This distinction is, however, adequately explained in the two hypotheses dealt with in this article on vision and the previous one on audition (see NATURE, September 2, p. 316). In the case of vision only three heavily damped responders are postulated in the single octave, whereas for hearing twelve lightly damped responders were postulated for each octave. The latter secures the finer analysis of which the ear is known to be capable, whereas the former agrees with the known lack of spectrum analysis in the eye. It still leaves power to discriminate twenty or thirty distinct colours in the whole spectrum, however, for if one pendulum CD be used as stimulus it may be changed gradually in length by twenty or thirty steps from the frequency corresponding to the violet responder to that of the red one, and at each adjustment the relative amplitudes of the three responders are appreciably different.

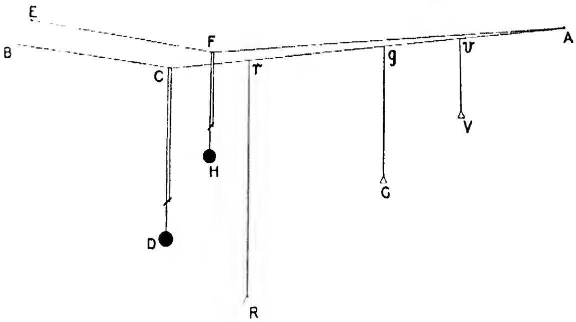

FIG. 1

Subsidiary Hypothesis.—To meet the cases of colour blindness, one or more of the three responders is supposed to be absent or *abnormal* in frequency or damping. This opens out a wide field of possibilities.

To explain the time effects (the tenth of a second needed to acquire or lose the full visual sensation) a subsidiary hypothesis is put forward. The vibratory response is supposed only to initiate the process of vision by starting some changes of a physiological or chemical nature which in turn affect the nerves, these changes being, however, quantitatively dependent upon their vibratory initiation. When the light stimulus ceases the vital activities are assumed to restore the changed materials of the retina to their normal states. Both changes are supposed to occupy something of the order of a tenth of a second.

The object of the present article was simply to show whether a syntonic hypothesis is adequate to explain the chief facts of vision. The conclusion is in the affirmative. But the hypothesis is not thereby established. We can only say that, if the hypothesis be true, colour vision would be, in the main, as we now experience it.

To suggest the exact nature of a probable or possible mechanism to carry out this syntonic hypothesis is another matter and beyond the scope of the present article. It was, however, discussed by Sir Oliver Lodge at the Bournemouth meeting of the British Association in 1919.

Obituary.

PROF. J. A. POLLOCK, F.R.S.

PROF. JAMES ARTHUR POLLOCK, professor of physics in the University of Sydney since 1899, who died after a short illness on May 24, at the age of fifty-seven years, was a fine physicist and a man of exceptionally high, loyal, and unselfish character. He was born in or near Cork, and was educated at the Manchester Grammar School and the Royal University of Ireland, taking an engineering degree. He and his brother Hugh Pollock (they were inseparable), were intended to enter some linen-manufacturing business in which his family were interested; but this proving a disappointment in some way, the young men with their father and some other members of their family went to Sydney about 1884. Arthur Pollock obtained an appointment at the

Sydney Observatory, but soon gave it up to enter as a student at the University, to the great regret of the Government Astronomer, H. C. Russell. He took the B.Sc. with the university medal for physics in 1889, and in 1890 was appointed demonstrator in physics under Sir Richard Threlfall, who at that time occupied the chair of experimental physics. On Threlfall's return to England in 1899 Pollock succeeded to the professorship, which he held up to the time of his death. He was president of Section A of the Australian Association for the Advancement of Science in 1909, was secretary of the Royal Society of New South Wales for the last eleven years of his life, and was elected F.R.S. in 1916.

When the Australian Mining Battalion was formed for work in France about 1915, Pollock at once joined with the rank of captain—the fact that he was fifty years old at the time naturally made no difference to a man of his character. Soon after he got to France he was put in charge of the school for training officers in "listening" underground by means of geophones and related devices. The school was near Poperinghe, within easy reach of Messines and other points of the line where tunnelling was in progress, and he took his full share in the nervous work of estimating how near our tunnels were to the German works. It was characteristic of him that having noticed that in binaural listening with geophones some observers were much more effective than others, he used his opportunities to estimate the minimum retardation of phase which would cause the sound to go "round the head." He finally discovered a young Russian who was so sensitive that he could point the geophone indicator in the direction of the sound with an accuracy of the same order as is attainable by visual means!

After the mining period was over Pollock was moved to Farnborough, where he worked at the problems of aeroplane navigation with the rank of major until the end of the war; but his real contribution to the final victory lay in the way he conducted the school at Poperinghe, where all instruction in "listening" was practically in his hands.

Pollock's experimental work in physics, contained in some twenty papers, is characterised throughout by his striving for accuracy and the avoidance of ambiguity. His early training at an observatory coloured all his work. Whatever the apparatus was, the best result must be got out of it, and when the work was published nothing must appear that was not really essential. His skill in adjusting instruments has probably scarcely ever been equalled, as may be seen by reference to a joint paper on a gravity balance (Phil. Trans., 1899, Vol. A, 193). In this work, whatever degree of success was attained may be attributed mainly to Pollock's skill and devotion; the late Mr. Duddell—no mean judge in such matters—once told the writer that had the thing not been done he should have regarded it as impossible.

During the years 1890 to 1895 Pollock was greatly interested in optical experiments. He had acquired great skill in making the adjustments required when using the Michelson-Morley classical apparatus, and with it made some observations of the effect of the velocity of a stream of water on light passing through it. Like many other of his experiments no publication was made, because he considered that the conclusions he came to did not constitute an advance on existing knowledge.

After 1900, for some years Pollock's work was mainly directed to establishing the relations between the geometrical constants of a conductor and the wavelength of the electromagnetic radiation obtained from it. The accurate figures obtained were very welcome at the time, and he returned to the subject at a later date. The apparatus was then used for the determination of the specific inductive capacity of a sheet of glass at high frequency 24,000,000 (Pollock and Vonwiller). Measurement was repeated at a frequency of 50, and no appreciable difference in specific inductive capacity was found. This work was then extended to Selenion by Vonwiller and Mason as a supply of well-purified material was available. The value obtained, again practically the same whether the frequency was high or low, namely, 6·13 at 16° C. by low frequency and 6·14 by high frequency at 23·6° C., is probably the most trustworthy figure extant for the material in the physical state described in the paper. As the measurement was not made in Germany, it is doubtful whether it will ever reach a text-book.

The above investigations were followed by an experimental and theoretical investigation of the application of the ionic theory of conduction to the carbon arc—especially in regard to the phenomena of "relighting" (Pollock, Wellisch, and Ranclaud), 1909, but for several years Pollock's experimental work was much interrupted by the illness of his brother, to whom he was devoted and to whom much of his scanty leisure was given—he died some years ago.

Probably the most important work done by Pollock was his investigation of the ions of the atmosphere (*Phil. Mag.*, 29, 1915, pp. 514 and 636, and Proc. Roy. Soc. N.S.W., Oct. 1909). Starting with the "large ions" discovered by Langevin, Pollock showed that their mobility was definitely related to the relative humidity of the air; applying a thermo-dynamic argument to his observations he concluded that the large ions condensed water in the liquid phase. He then discovered a new class of ions intermediate in mobility between Langevin's ions and free ions, and by the same thermodynamic argument indicated that in this case the ion was weighted with water in the vapour phase.

The two papers quoted give a very good idea of Pollock's powers as a physicist, since he allowed his scientific imagination more scope than usual. Among minor contributions his description of an automatic Sprengel pump and an investigation of the mode of formation of very small bubbles in frothing solutions may be mentioned. In fact, his exposition of froth formation (*Phil. Mag.*, 1912) is exceptionally clear and judicious.

In 1914 Pollock returned to his observations on the relation of the length of electromagnetic waves to the length of a "straight terminated" rod in which they are generated, and more recently was applying his experience in acoustics, obtained during the war, to the investigation of the action of the stethoscope and to the study of the velocity of sound through earth.

As a colleague Pollock was ever cheery and obliging, but his courteous manner covered a character of great firmness, and if he had once made up his mind as to the propriety of any line of conduct he could not be turned

from it. On the whole, both Pollock's life and work were determined by an almost Roman sense of duty, and his output of scientific investigation (considerable though it was) was limited by the severe view he took of his obligations as a teacher.

PROF. TADEUSZ GODLEWSKI.

TADEUSZ GODLEWSKI was born on January 4, 1878, the youngest son of the distinguished plant physiologist, Dr. Emil Godlewski, Sr., who was for many years a professor in the Jagellonian University of Cracow. After receiving his early education at the St. Anna School in Cracow, Godlewski entered the philosophical faculty of the Jagellonian University in 1897, and graduated in 1903, the subject of his dissertation being the osmotic pressure of solutions. Between 1901 and 1903 he worked under Prof. A. W. Witkowski as demonstrator in the University Physical Laboratories, and then proceeded to Stockholm for a year's post-graduate study with Prof. Svante Arrhenius, from whose laboratory he published a paper on electrolytic dissociation.

In October 1904 Godlewski travelled to Montreal and entered the laboratory of Sir Ernest Rutherford, by whom he was initiated into radioactive research, and under whose guidance he published three papers on radioactivity during the following year. On his return to Poland in 1905 he was appointed demonstrator, in 1906 assistant professor, and in 1910 full professor of physics at the Technical High School, Lwów (Leopol or Lemberg, Poland), and for the academic year 1918–1919 he was elected Rector of that institution. In 1921 he was elected a Corresponding Member of the Polish Academy of Science and Letters in Cracow. He died on July 28, 1921, from the effects of a slow poisoning, resulting from a coal-gas leak in his laboratory.

Godlewski's later work was devoted mainly to radioactive and electro-chemical problems, and he published numerous original papers. His nature was kindly and lovable, and those who knew him could not but feel the charm of his personality. During the period of my association with him in Vienna in 1915, he looked forward to the dawn of better days for a united Poland, and I well remember his unutterable grief at the death of his friend Smoluchowski in 1917, when he wrote me: "This is truly the greatest calamity that could have befallen us." During the last few years Poland has suffered the loss of several eminent men of science, whom she could ill spare, whose foresight and influence would have been invaluable in her policy of scientific and educational reconstruction. International science, too, mourns the loss of such men as Olszewski, Rudzki, Danysz, Smoluchowski and Godlewski. R. W. L.

M. L. FAVÉ.

THE death of M. Louis Favé after an illness of several weeks occurred on July 31. Before his retirement M. Favé was the chief hydrographic engineer to the French Navy, and the greater part of his forty years' administrative service was devoted to the study of tides, to coastal surveys, and to the configuration of oceanic basins. He was interested chiefly in the observational side of such work, and especially so in connexion with the invention and construction of new scientific instruments for those purposes. Among these may be mentioned a very efficient device for the damping of small periodic movements in such instruments as mariners' compasses; he also devised instruments for the navigation of balloons.

His most outstanding achievement, however, for which M. Favé deservedly received great credit, was the invention of the Favé tide-gauge. This ingenious instrument, designed for the continuous registration of tidal heights in the open sea, was invented in 1887 and has received continuous development. It is essentially a pressure gauge and registers the variations in pressure by means of two Bourdon gauges on a rotating piece of smoked glass, from which measurements are made with the aid of a microscope. One of the advantages of the instrument is that it can be left without attention at the bottom of the sea for a fortnight. By various devices M. Favé was enabled to obtain records in fairly deep water, and recently he claimed successful operation at a depth of 400 metres. The applications of such an instrument as this are very interesting and important; for instance, Whewell suggested the existence of a point about half-way between England and Holland, where the vertical movement of the sea is zero, and the Favé gauge has been used to supplement other observations, so proving the existence of such a point.

The news of M. Favé's death will be received with much regret by all who are interested in hydrography.

THE death is announced from New York of Dr. Jokichi Takamine, at the age of sixty-eight years. Born in Japan, Dr. Takamine was educated at the Imperial University and afterwards in Glasgow at Anderson College. While in Glasgow he worked at the enzymes of fungi and introduced the useful preparation known as "taka-diastase" He returned to Japan in 1881 and, after marrying an American lady, went to the United States in 1890, became attached to Messrs. Parke, Davis and Co. as consulting chemist, and set up a laboratory of his own His chief scientific achievement was the separation of adrenaline from the supra-renal bodies. Much of his time was spent in travelling between the United States and Japan. He thus played an important part in facilitating the relations between these countries.

WE notice with regret that Dr Sophie Bryant has met her death by accident near Chamonix. She left her hotel at Montanvert on August 15 to walk to Chamonix, and her body, bearing marks of several injuries, was found on August 28. She appears to have wandered from the usual path and to have fallen on to a rock. Dr. Bryant was the first woman in the British Isles to receive the degree of doctor of science, and she was headmistress of the North London Collegiate School for Girls from 1895 to 1918.

WE regret to see the announcement of the death, on August 27, of Dr. David Sharp, F.R.S., at the age of eighty-one years.

Current Topics and Events.

H R H. THE PRINCE OF WALES, who is patron of the Ramsay Memorial Fund, has consented to unveil on Friday, November 3, at 12 noon, the memorial tablet of the late Sir William Ramsay which is being placed in Westminster Abbey. The tablet has been executed by Mr. Charles L. Hartwell and was exhibited at the Royal Academy this summer. Invitations will be sent out in October. Any communications with respect to the unveiling should be addressed to the organising secretary of the Ramsay Memorial Fund, Dr. Walter W Seton, at University College, Gower Street, London, W.C 1

"INTELLECTUAL CO-OPERATION" is the phrase, sufficiently comprehensive, employed by the Council of the League of Nations to designate the field of investigation of a commission set up by it in May last This body, consisting of twelve members, among whom are Profs Henri Bergson (president), Gilbert Murray (vice-president), Madame Curie-Sklodowska, and Prof. A Einstein, held its first session at Geneva on August 1-5 The commission had been given a free hand to define its own programme with due regard to existing national activities and existing organs of international intellectual life The following were among the topics selected for consideration the desperate economic condition of the *intelligenzia* in some European countries—notably Austria and Poland, the protection of proprietary rights in scientific discoveries and ideas, the establishment of an international *entente* for the examination and publication of archæological monuments, inter-university relations, and an international organisation of bibliography All these questions have been referred to individual members of the commission or to sub-commissions for the preparation of reports with the view of taking further action As for co operation in scientific research, the commission, anxious not to interfere in the organisation or work of the scientific societies, decided that this should be left to the initiative of the societies themselves Another question on which the commission found itself unable to take any useful action was the publication by common consent of workers in all parts of the world of discoveries relative to toxic gases and the development of chemical warfare It decided to reply to the Reduction-of-Armaments Commission, which had referred the question, that it was unable to suggest methods whereby this result might be brought about

A REPORT of the European Health Conference (League of Nations), held at Warsaw in March last, has been issued. It contains a general report of the work of the Health Organisation since its initiation in 1920, a summary of information received from delegates, minutes of plenary meetings, and reports of various sub-committees on the cost of measures required and the needs of various states, with four useful charts showing the epidemic situation in Eastern Europe Dr Rajchman, the secretary, summarised the results achieved by the conference, and explained the plan of campaign devised to fight epidemic disease. That there is need for this will be realised when it is stated that during 1922 there were many districts in Eastern Europe with thousands of cases of typhus and relapsing fevers, and cholera.

FROM the Otago University Museum we receive the Annual Report for the year 1921, drawn up by the curator, Prof. W. B Benham, professor of biology in the University, who says that "in the not distant future it will be necessary to build a new Biological Department altogether distinct and separate from the Museum, and to divorce the functions of professor and curator, now nominally carried on by one individual." Fortunately, Prof. Benham has a most capable assistant in Mr. H. D. Skinner, who is well known as an ethnologist, but that branch of science and his duties as Hocken Librarian absorb all his time To judge from the work recorded in the present report, there is more than enough to occupy all the energies of a full-time curator, as well as the additional technical assistants for whom Prof. Benham calls. We note that the Chinese colony in Dunedin has subscribed the sum of 35*l.* to provide cases for a recent donation of Chinese objects When the rest of the population takes equal interest in the Museum, the just demands of Prof. Benham may perhaps be fulfilled

THE Trieste Academy of Science and Art announces a competition for the best contribution upon the subject of "Partial Differential Equations of Maxwell-Lorentz" Three prizes will be given The competition is open to all nationalities Contributions must bear a pseudonym and be accompanied by a sealed envelope with the name and address of the competitor The latest date for the receipt of contributions is December 31, 1922 The papers will be published in the Annals of the Academy. Further information may be obtained from the secretary of the Academy of Science and Art, Trieste, Hugh Foscolo Street, 2

A CENTENARY celebration of the birth of Gregor Mendel is to take place at Brunn, Czecho-Slovakia, on September 22-24 A monument to Mendel's memory was erected at Brunn in 1910, and in the succeeding twelve years the fundamental significance of the principle which he discovered has been still more widely recognised and applied in biology. The programme of the celebration will include addresses on the personality and work of Mendel, as well as papers by prominent Mendelians from various countries, and an excursion to neighbouring caves and to Mazocha The programme is in the hands of a local committee, and inquiries or contributions should be sent to Dr. Hugo Iltis, Backergasse 10, Brunn, Czecho-Slovakia

A SUMMARY of the weather for the past summer, comprised by the thirteen weeks ended August 26, is given in the *Weekly Weather Report* published by the Meteorological Office for the week ended August 26. The highest temperature in any district of Great Britain was 86° F, which occurred in the north-west of England. The north of Scotland was the only district where the thermometer failed to touch 80° F, Mean temperature was everywhere below the normal.

the deficiency ranging from 2°·6 in the east of Scotland and 2°·5 in the west of Scotland to 1°·3 in the north-east of England. Rainy days were slightly above the normal except in the north-east of England and in the Channel Islands The total rainfall was in excess of the normal in all the eastern English districts and in the south-west of England, the excess was greatest in the Midland Counties, amounting to 2·44 in, the next largest excess being 0·83 in., in the north-east of England. The duration of bright sunshine was generally deficient and ranged from 7 hours per day in the Channel Islands to 4·6 hours in the north of Scotland At Greenwich the mean temperature for the three summer months, June to August, was 60° F, which is 4° cooler than for the corresponding period last year, June was slightly the warmest month, and after June 19 the thermometer failed to touch 80° during the remainder of the summer, a feature similarly outstanding in 1920 and 1910 The total rainfall for the three summer months in London was 6 7 in, and July was the only month with an excess of rain, the total for the three months was a quarter of an inch above the normal and more than five times greater than in the corresponding three months last year Bright sunshine in London was 150 hours less than in the corresponding quarter in 1921, August was the least sunny month

THE Report of the National Physical Laboratory for the year 1921 covers more than 200 pages and gives outlines of many of the researches which have been in progress during the year, with sufficient diagrams to enable the reader to understand the methods and apparatus in use The outstanding events in the history of the Laboratory for the year are —the presentation of a bas-relief of Sir Richard Glazebrook executed by M Cluysenaar of Brussels, which has been erected in the hall entrance of the administrative building with the back of Sir Richard's head towards the entrance, the unfortunate disaster to airship . 38 at Hull, which involved the loss of two of the most valued members of the aeronautics' staff, and the completion of the new buildings for the Admiralty Research Laboratory, and some of those sanctioned by the Treasury in 1920 Funds for the Physics building and for the extension of the Metallurgy building are not yet available Research for the fighting services has grown considerably during the year, and the Research Associations established by the Department of Scientific and Industrial Research have been responsible for an extensive programme of work, though with one or two exceptions all departments record a decrease in the number of tests made Dr. J A Harker, one of the original members of the staff, has resigned to take up a consulting practice, and Dr G. W. O Howe is going to Glasgow University as professor of electrical engineering.

WE learn that Messrs Taylor, Taylor, and Hobson, Ltd, of Leicester, the makers of the well-known Cooke lenses, have now become associated in business with Messrs Bellingham and Stanley, Ltd, of 71 Hornsey Rise, London, N 19. It is hoped that by pooling the knowledge and resources of the two firms the interests of the British optical industry will be promoted, and that additional economy of manufacture will be secured.

WE have received a copy of the first number of the *Record of Photography*, a journal to be issued monthly by the Professional Photographers' Association It is devoted to the interests of professional and trade photographers and is not to compete with any existing publications It has the feature, probably unique, that the pages of text are each backed with advertisements, so that any part may be cut out for filing without the loss of other matter (except advertisements) on the back Accompanying it are two good reproductions of portraits by Mr Pirie MacDonald of New York.

THE last number received of the *Revista de Sciencias* (Rio de Janeiro) contains articles on the new survey of Brazil, Poincaré's mathematical philosophy, clinical forms of *Granuloma ulceroso*, and the dynamic theory of the seismograph There are notes on the mathematical theory of muscular work, on the occurrence of rare earths in Brazil, the determination of the constants of a thermionic valve, geological notes on the Ceara region, notes on some plants which furnish material for the study of protoplasmic currents, and a general summary on the mineral resources of Brazil as well as shorter notes and articles on other subjects

WE have received a catalogue of microscopes and microtomes from the Bausch and Lomb Optical Co (37 and 38 Hatton Garden, E C) A great many different types of microscope stands are listed, ranging from the simplest to complex models for advanced research and of the binocular pattern Achromatic, fluorite, and apochromatic objectives and eye-pieces of all types are supplied, as well as all the usual accessories The microtomes include the well-known small and large Minot forms Many of us had an opportunity during the war of using the Bausch and Lomb instruments, and found them eminently satisfactory, both mechanically and optically The prices compare favourably with those of other makers

MESSRS GEORGE BELL AND SONS, Ltd, will publish this month, under the title of "Bell's Mathematical Tables," a new book by Dr L. Silberstein, suited to the requirements of the mathematician and the theoretical physicist The work will be in two parts, the first containing the usual logarithms of numbers and of the fundamental trigonometric functions The second and larger part will contain a collection of mathematical formulæ, definitions, and theorems, together with tables of the more important special functions, such as elliptic integrals, Bessel functions and spherical harmonics, Fresnel integrals, etc Another book in Messrs Bell's list of announcements is "A Text Book of Machine Construction and Drawing," by H E Merritt and M Platt, the object of which is to provide a thorough and comprehensive exposition of the subject for engineering students It will cover intermediate requirements, and be of service to more advanced students as a book of reference A further book by the same authors on the subject of machine design for the use of degree students and designers is in active preparation

Our Astronomical Column.

AUGUST METEORS.—The great shower of August Perseids was not well observed this year in consequence of cloudy weather and moonlight. A rich display of Cygnids was, however, witnessed during the last half of the month from the point $291° + 50°$ near θ Cygni. The individual members of this stream were brilliant with swift motion and short paths. At the end of their flights many of them burst with a sudden acquisition of brightness. The shower is fairly well known and gave an abundant display in 1893. In that year, between August 4 and 16, 28 of its meteors were seen at Bristol, while 40 were recorded by Mr. Corder at Bridgwater, and 30 by Mr. Blakeley at Dewsbury. A full description of the shower appeared in the *Observatory* for September 1893, and the explosive character of the meteors was specially pointed out. The visible strength of the shower varies from year to year, but its period has not yet been ascertained; further observations are required of this particular stream, for it is certainly one of the most important of the many systems which are in contemporary activity with the well-known Perseids.

MARS.—The first drawings of Mars at the present apparition are published in *L'Astronomie* for July. They were made by M. Mentore Maggini at Catania. One, made on May 23, accords with the description of M. Jarry-Desloges of the paleness of the dark markings at this period, presumably due to their being covered by a veil of mist or dust. This seems to have dissipated by June 1, a sketch on that date showing these regions dark, especially Syrtis Major; the southern end of it is flanked by two brilliant white patches. Nepenthes is very prominent, and widely double. The drawing indicates 15 other canals. Both polar caps are shown, the southern being the larger. Dr. Fountain in the B.A.A. Journal for June 28 ascribes the red colour of the Martian deserts to ferric oxide, and suggests that owing to the escape of the lighter gases the Martian atmosphere may be relatively rich in oxygen, so that meteoric dust would tend to become oxidised.

THE FRYE REFLECTING TELESCOPE.—The 100-inch Hooker Telescope is not long to remain the largest in the world. Mr. T. S. H. Shearman, Government Meteorologist at Vancouver, has successfully cast a speculum of 10 feet diameter and 50 feet focal length which is to be erected in the new observatory planned by Mr. Chas. H. Frye at Seattle. This observatory is to be open to the public at certain times, the telescope will then be used in a horizontal position, being fed with light by a plane mirror; but when it is employed for the photography of nebulæ or other faint objects it will be pointed directly at the sky. The cost of the instrument is in the neighbourhood of 300,000 dollars, and is apparently being borne wholly by Mr. Frye. The above particulars are taken from Circular No. 1 of the Frye Observatory, which also states that Mr. Shearman expected to make the first astronomical observation with the new speculum before the end of July.

VARIABLE STARS NEAR M. 53.—Dr. Baade gives in *Mitteilungen der Hamburger Sternwarte*, Bd. 5, No. 16, an account of a photographic search for variables near the globular cluster M. 53. It resulted in the discovery of 7 variables within a region extending from R.A. $13^h\ 1^m$ to $13^h\ 13^m$, and from Decl. $+17° 39'$ to $+19° 41'$. Five of them are of the cluster type, with periods between $\frac{1}{2}$ and $\frac{2}{3}$ of a day. Applying Shapley's rule for the absolute magnitudes of these stars, their distances, in units of 1000 light-years, are 16, 20, 23, 41, 62 respectively. The last named, the mean magnitude of which is 16·25, appears to be a member of the globular cluster, though distant $34'$ from its centre. The others are probably unconnected with the cluster. Since the latter is in galactic latitude $79°$, the results suggest a much greater extension of the sidereal system in this direction than that indicated by Prof. Kapteyn, who concluded that the star-density became sensibly zero at a distance of some 10,000 light-years towards the galactic poles.

ABBREVIATIONS OF CONSTELLATIONS' NAMES.—In the printing of Star Catalogues in which reference is made to the names of the constellations, a large amount of valuable space is wasted in consequence of the lack of a standard system of an abbreviated nomenclature. At the meeting of the International Astronomical Union held at Rome in May last, the Commission on notation, units, and economy of publication decided on a system of abbreviations which involve only three letters for each constellation. Thus, to give a few examples, And is Andromeda; CMa, Canis Major, CVn, Canes Venatici, Gem, Gemini; etc. In the Harvard College Observatory Bulletin, No. 771, it is stated that this system will be adopted forthwith. It is expected that it will now be used universally, since it is a great economy and convenience in printing, especially when large catalogues of stars with their magnitudes, positions, proper motions, spectrum types, parallaxes, etc., are in hand.

NEW NEBULÆ.—In the Harvard College Observatory Bulletin, No. 773, it is announced that Mr. Donald H. Menzel has found recently approximately two thousand new nebulæ on ninety photographs made with the 24-inch Bruce telescope at Arequipa, the southern hemisphere station of the Harvard College Observatory. Most of the new objects are south of declination $-45°$; their positions and descriptions will be published later. Of the eight hundred brightest nebulæ found by Mr. Menzel, about thirty-five per cent. appear to be spirals, *i.e.* they show spiral arms or the characteristic spindle form. The majority of the other bright objects are stated to belong probably to the type designated by Hubble as globular nebulæ. It is interesting to note that the total number of nebulæ now recorded is nearly 20,000.

A VERY MASSIVE STAR.—Much attention is now being given to the determination of the masses of stars, so that any star of excessive mass becomes at once an interesting object. Dr. J. S. Plaskett, Director of the Dominion Astrophysical Observatory at Ottawa, describes (Mon. Not. R.A.S., vol. 82, p. 447) the star B.D. $6°$ 1309, No. 2422 of the Harvard Revised Photometry, which consists of two very bright Oe stars, *i.e.* stars at nearly the highest temperature, 10,000 light years away from us; they revolve around one another in an elliptic orbit in a period of 14·414 days, but are separated by a distance of 90,000,000 kilometres. The brighter of the two stars has a probable mass of at least 86 times that of the sun, a density of 0·01, and an absolute magnitude of $-5·65$. The fainter star has a mass of 72 and is of the same density, its absolute magnitude being $-5·4$. The absolute magnitude of the system as a whole is $-6·3$, which is the greatest so far determined.

Research Items.

Neolithic Script in India.—The recent discovery of two neoliths, one from Chota Nagpur, the other from Assam, said to be marked with decipherable scripts, has attracted some attention. On one of these Prof. Bhandarkar read the word "Maata," assumed to mean "a headman or chieftain." The script is believed to be that known as the Brahmi, which, according to Bühler, was introduced in India from Semitic sources about 800 B.C. Unfortunately, however, there is no evidence that this character was ever written from right to left. The question of these neoliths has been examined by Mr. Hem Chandra Das Gupta in the Journal of the Asiatic Society of Bengal (vol. xvii. No. 2), who points out that the evidence of provenance and of the fact that the inscriptions date from the Neolithic Age is far from satisfactory. Symbols like letters of the alphabet have been found in European soil painted upon pebbles belonging to a stratum between the Palæolithic and Neolithic Ages at Mas d'Azil in France, but scholars are still doubtful whether these so-called inscriptions form a scientific basis for investigation of the origin of the alphabet. The same may be said of these recent Indian discoveries.

The Swastika, Gammadion, Fylfot.—The familiar symbol known in India as the Swastika, or omen of good luck, and in the West as the Gammadion or Fylfot, has generally been interpreted to represent the sun in its apparent course. Its origin has been investigated by Mr. Harit Krishna Deb in the Journal of the Asiatic Society of Bengal (vol. xvii. No. 3). He suggests that it is based on the method of writing the sacred syllable Om, afterwards typical of the Brahmanical triad of deities. This, when written in the Brahmi character, takes the form of two crossed pot-hooks, which he regards as the earliest form of the Swastika. This theory meets with the serious objection that while this symbol comes down from the Bronze Age at least, and is found on pottery from the Third City at Hissarlik, the Brahmi alphabet, according to Buhler, was derived from a Semitic source about 800 B.C. Mr. H. K. Deb suggests that some of the Brahmi characters may be of indigenous origin in India, while others were adopted from Semitic scripts, but there is no evidence of this. Nor is there any reason to believe that the Swastika was adopted for the first time in India The interpretation now suggested may be regarded as not proven, unless we are prepared to believe that in this specialised form it is peculiar to India, and the solar explanation may for the present be regarded as holding the ground.

Insectivora from the Congo.—The collections made by the American Museum Congo expedition are gradually being worked out and the results published. The latest section dealt with concerns the Insectivora and was the work of the well-known American zoologist J. A. Allen, who, alas, died without seeing the final proofs (Bull. Amer. Mus. Nat. Hist., vol. xlvii.). The Soricidæ were described in the same Bulletin in 1916 by N. Hollister, but the gist of his work is here repeated to make the whole subject complete. Fifty-two species and subspecies are chronicled, of which only two are, however, new.

Foraminifera of the Atlantic Ocean.—The third part of an important monograph on the Foraminifera of the Atlantic Ocean by J. A. Cushman has just made its appearance (Bull. U.S. Nat. Mus., 104). The first part, dealing with the Astrorhizidæ, was published in 1918 (see Nature, vol. cii. p. 51), and the second on the Lituolidæ in 1920. The present part includes the family Textulariidæ, which is apparently more primitive than most of the other families of the Foraminifera, and follows the Lituolidæ in its general characters, a number of the simpler genera being wholly or in part composed of species with arenaceous tests. In the most primitive subfamily, the Spiroplectinæ, a coiled development makes up a considerable portion of the test. A number of new species are described, and there are twenty-six excellent plates.

Hawaiian Natural History.—The Bernice Pauahi Bishop Museum of Polynesian Ethnology and Natural History continues its useful career, and its "Occasional Papers" have reached the eighth volume. Three of the latest numbers bearing on natural history are now before us. C. Montague Cooke, jr. (vol. vii. No. 12), supplies "Notes on Hawaiian Zonitidæ and Succineidæ." Among the former the author includes Vitrina, which has long been placed in a family of its own; he elevates Godwinia into a subfamily on anatomical grounds; and founds a new genus Nesovitrea for the *Vitrea pauxillus* of Gould. To the Succineidæ he adds two new species of Catinella, and creates a new genus, Laxisuccinea, for two new fossil species. Adequate illustrations of anatomical details are given in the text, and there are two plates of the shells from the pencil of Miss Winchester, which is a guarantee of their worth. The Stomatopoda in the Museum are the subject of a paper by C. H. Edmondson (vii. No. 13). The collection comprises 53 specimens, of which one is new. The same writer also treats of the Hawaiian Dromiidæ (viii. No. 2), amounting to four species, of which one, *Dromidia hirsutissima* (Lamk), recorded by Dana, has not been seen by him, and he considers its occurrence doubtful.

Ecology of South Australia.—An interesting contribution to the study of arid regions, with special reference to the vegetation, has been prepared by Mr. W. A. Cannon ("Plant Habits and Habitats in the Arid Portions of South Australia." Washington: Carnegie Institution, 1921). The importance of bringing under cultivation those portions of the earth's surface which, at present, are of more or less desert nature, is becoming increasingly important in face of the growing demands for food of the world's population. The studies of the physical, geobotanical, and ecological characteristics of such areas are being carried out by our American friends with their typical vigour and freshness of outlook and are already proving of practical value. In the work under notice the varying vegetational features are correlated with the rainfall in the districts which they inhabit, an arbitrary classification of regions being based on the annual amount of rain. It is shown that in South Australia as a whole the flora is distinctly of a xerophytic type, and that of the dry northern portion differs from the rest only in degree and not in kind. The total absence of deciduous species is noteworthy. The morphological and ecological peculiarities of the species of Acacia and Eremophila are especially considered. The halophytes, mainly species of Chenopodiaceæ and Amarantaceæ, constitute the most prominent element of the flora of the very dry districts. *Triodia irritans* and *Spinifex paradoxus* are among the most frequent grasses. The work is illustrated by 32 pages of photographs, some showing characteristic landscapes and vegetational features, and others peculiarities of root, shoot or leaf morphology. There is a bibliography and a summary of contents but no index.

EXPERIMENTAL SILICOSIS OF THE LUNGS.—It is well known that the inhalation of dust particles in various industries may be provocative of serious fibrotic and other changes in the lungs. This obtains particularly among grinders, file-makers, and clay workers, while other dusts, notably coal dust, are much less harmful. The miners on the Rand suffer much from silicosis, due to the inhalation of silica particles derived from the quartz, and A. Mavrogordato has investigated the question experimentally by causing guinea-pigs to breathe dust-laden air of various kinds over varying periods (Publications of the S. African Institute for Medical Research, No. xv. 1922). He finds that the solubility and chemical activity of dust, *e.g.* silica, are the important factors inducing fibrotic changes in the lungs, hardness and sharpness of the particles being of little importance. The majority of the particles entering the lungs are less than 1μ in diameter. The particles do not penetrate the tissues, but the tissues take up the particles by means of phagocytic cells. The silica-laden cells block lymphatics and thus prejudice the lungs' ability to deal with infections, and hence secondary tuberculous infection is common.

THE BACTERIAL FLORA OF GREENLAND.—Samples of the soil and of the fæcal matter of polar animals collected by Dr. T. Wulff in North Greenland in 1916 and 1917 were examined bacteriologically by Dr. C. Barthel in Copenhagen. Nineteen species of bacteria were isolated from the soil and identified. They included such well-known forms as *B. subtilis*, *S. flava*, *B. mesentericus*, and *B. zopfii*. Almost all the soils contained nitrates, and in some, nitrifying micro-organisms were detected. In addition, denitrifying, ammonising, urea-fermenting, and butyric forms were found. In the fæcal matter of such animals as the blue fox, arctic hare, crow, seal, polar bear, lemming, and white partridge a variety of aerobic and anaerobic organisms was isolated, including *M. candicans*, *Strep. fæcalis*, *B. putrificus*, and others. The results obtained indicate the ubiquity of many species of bacteria, both simple saprophytes of the soil and of the animal intestine, and special putrefactive and nitrifying forms. (Recherches bactériologiques sur le sol et sur les matières fécales des animaux polaires du Groenland Septentional. Den II Thule Ekspedition til Grønlands Nordkyst 1916–18. Nr. 1. Copenhagen, 1922.)

PRECIPITATION IN THE UNITED STATES.—A notice of the new precipitation section of the Atlas of American Agriculture is given by Prof. Robert De C. Ward in the U.S. *Monthly Weather Review* for March. Notice has previously been given of the monthly, seasonal, and annual rainfall charts, but the fresh material to complete the precipitation section has recently been sent in the form of loose sheets to some to whom the material is of immediate practical use, prior to the final issue. The records are for a uniform period of 20 years, 1895–1914, from about 1600 stations, and in addition shorter records are used from about 2000 other stations. The object of the publication is to benefit agriculture, and it lays marked emphasis upon the departures which may be expected from the average, so that the farmer may decide for himself what crops he may plant with the greatest probability of success. Numerous charts and graphs are given. The percentage of the annual precipitation occurring between April 1 and September 30 is highest, more than 70 per cent., over most of the great agricultural region of the eastern United States, embracing the eastern Plains and Prairie States. Frequency and intensity of precipitation are shown in great detail for the whole country. Day and night rain percentages are separately given, and it is shown that over the great agricultural states east of the Rocky Mountains large sections receive more than half, and considerable areas receive about two-thirds of their warm season rains at night, and there is therefore much less rapid evaporation. Snowfall is considered, and the annual number of days with thunderstorms, and the distribution of fog and cloudiness are given.

THE STANDARD ATMOSPHERE.—In aeronautical and artillery calculations it is now necessary to know the condition of the atmosphere at heights up to 20 kilometres with a degree of accuracy not previously required, and each nation is at present concerned to define a mean condition from which the actual condition within its borders at any time will deviate only by relatively small amounts. It has been found that Toussaints's formula $t - 15° = 0{\cdot}0065z$, where z is the altitude in metres, gives the mean temperature throughout the year up to 10 kilometres, above which the temperature is constant at $-55°$ C. The observations in the United States set on foot by the American National Advisory Committee for Aeronautics have, according to Report No. 147, prepared by Mr. W. R. Gregg, established the applicability of the formula to that country. The report also shows that the hypsometric equation based on Toussaints's formula leads to values of the pressure in agreement with observations, and that the density at any level may be calculated from the pressure and temperature by the "perfect gas" equation.

SENSITISERS FOR THE EXTREME RED.—In the *British Journal of Photography* for August 11, Drs. C. E. K. Mees and G. Gutekunst describe three new sensitisers for the extreme red, giving their properties and methods of preparation. They are suitable either for adding to the emulsion or for bathing ready prepared plates, with the exception noted below. Beta-naphtha-cyanole gives a strong maximum at 690 $\mu\mu$, and sensitises the green markedly less than pinacyanol. Acetamino-cyanole added to an emulsion gives a strong maximum at 730 $\mu\mu$; but in dilute aqueous solution as prepared for bathing plates it appears that the acetyl is hydrolysed off, and its effect is much restricted. Kryptocyanine gives a very strong maximum at 760 $\mu\mu$, and even at 850 $\mu\mu$ its sensitising power is greater than that of dicyanine, but beyond this point dicyanine is the more advantageous, and at 900 $\mu\mu$ kryptocyanine is almost useless. It does not sensitise in the green, and therefore may prove to be of special value in astronomical photography. On account of their peculiarly advantageous properties, naphthacyanole and kryptocyanine will be added to the list of sensitisers prepared and supplied by the Research Laboratory of the Eastman Kodak Company.

CANNED FOODS.—The Food Investigation Board has issued a special report (No. 10, 1s. 6*d.* net) on methods used for the inspection of canned foods (Part II., Canned Marine Products), compiled by Dr. William G. Savage. Attention is directed to the want of uniformity in procedure adopted by food inspectors. Much experimental work was carried out, but no tests were evolved more trustworthy than those in vogue for distinguishing swiftly and accurately between the safe, the dubious and the unfit tins. A "blown" tin is clearly a bad tin, but a tin with an abnormal shake sound or a springy top or bottom is merely a suspect sample. An organisation is suggested whereby better results and greater uniformity of inspection of canned foods might be obtained.

The First Messel Memorial Lecture.

DR. RUDOLPH MESSEL came to England in 1870 and died here in 1920. During the fifty years of his residence in this country he was engaged in the manufacture of sulphuric acid; he was a chemist of considerable repute, a fellow of the Royal Society, an accomplished and kindly man; by his will he left the whole of his fortune to the Royal Society and the Society of Chemical Industry. The council of the latter Society decided to set aside a small part of the legacy to found a series of Messel Memorial Lectures to be delivered by eminent chemists, each of whom is to receive a Messel medal. The first of such lectures was delivered in Glasgow last July by Prof. H. E. Armstrong, who was for very many years an intimate friend of Dr. Messel. The lecture is now published in the issue of the Journal of the Society of Chemical Industry for August 15.

The subject of the lecture is "Chemical Change and Catalysis," but Prof. Armstrong contrives to make sundry alarums and excursions into adjacent territories. There is a good and sympathetic account of the life and work of Messel, some amusing chaff of Ostwald and his school of ionic chemists, of Bancroft and his satellites, of colloid chemists and most other varieties of chemists, and an important contribution to our conceptions of the processes involved in chemical change. The lecture is important not so much because of the new matter in it, but because it puts the problem in an arresting manner and compels those readers who have any power of thought to cry a halt for a moment and consider first what the lecturer means, and then what the reader really thinks on this subject, and whether a good deal of what he has been in the habit of thinking is sound or not. Prof. Armstrong has long scoffed at text-books and has very successfully practised a method of teaching, the vital principle of which is to tell very little and make the pupil do a good deal of thinking and investigating. He continues to practise his method, if this lecture is any criterion of his present habits. The view he outlines is that no chemical change takes place except in the presence of an electrolyte, which he calls the "determinant", unless the substances concerned are in an electric circuit chemical activity is suspended. The work of Prof. H. B. Baker on the inactivity of perfectly dry substances is referred to several times. Electrolytic conductivity is discussed and the electrolysis of water; according to the lecturer this takes place in stages, the first stage being the formation of hydrogen peroxide; this unstable compound plays an important part in the association views of Prof. Armstrong: it is the first stage in the oxidation of hydrogen. The combustion of carbon monoxide, the oxidation of xanthin and hypoxanthin are discussed, and there is some account of catalysis, the action of enzymes, and the nature of acids.

The determination of Prof. Armstrong or perhaps his catalytic nature compels the mind of the reader to execute a sort of Brownian movement. He is driven from Gowland Hopkins to Meredith, from hydroxylation to Hudibras, from colloids to Lewis Carroll. And when he thinks, good, easy man, full surely the argument is ripening, he is switched off to a quotation from Erasmus Darwin or some new paradox about the basic properties of sulphuric acid, in a manner which those who are familiar with Prof. Armstrong's style will easily imagine, although they cannot—one scarcely knows whether to say fortunately or unfortunately—imitate it.

No one will begin this lecture without finishing it. No one will fail to be interested and amused; no one will come to the end without a stimulus to thought, a renewed curiosity as to chemical change, a new scepticism, and fresh ideas.

Stellar Radiation in the Infra-red.

DR. W. W. COBLENTZ[1] is developing the application of the thermocouple to the study of stellar radiation, and is deriving results of considerable interest and value, especially so far as red stars and red variables are concerned. The instrument he uses is not so sensitive as the photo-electric cell which is doing such delicate work in the hands of Guthnick, Stebbins, and others, but it lends itself more readily to the investigation of radiation in the longer wave-lengths.

Most workers engaged on spectrophotometric measures of the stars have concentrated on the visible spectrum. Dr. Coblentz uses various transmission screens which allow only radiation over fairly narrow regions of the spectrum to pass through to the thermocouple. He thus obtains the spectral energy distribution of the stars, and derives stellar temperatures agreeing fairly closely with the values obtained at Potsdam by Wilsing, Scheiner, and Munch. The chief interest lies in the extension to their work that he makes by using a water absorption cell, which is transparent for radiation between 0.3 μ and 1.4 μ in the infra-red, and does not absorb much radiation less than 0.5 μ in wave-length. When the transmission through a layer of 1 cm of water is only a small fraction of the incident radiation as in the case of α-Orionis and α-Scorpii, then Dr. Coblentz rightly concludes that the total radiation from these stars is far higher than is suggested by their visual magnitudes. It appears that we are faced with the fact that photo-visual methods can give us trustworthy magnitudes of stars only for a limited range, and that certain stars, especially novae, radiate with much greater intensity in the extreme ultra-violet than we are allowed by our atmosphere to measure, while others—the red stars and invisible dark stars—radiate with great intensity in the infra-red.

Even within the range where visual methods have prevailed, Dr. Coblentz shows that the failure to take into account the infra-red radiation has given much too small a value for the luminosity, or intensity of radiation, of the giant red stars. This may account for the puzzling fact which Prof. Russell recently proclaimed, that giant stars of all spectral classes were of about the same absolute magnitude. Dr. Coblentz's evidence is that this is not the case, but that the giant red stars are radiating far more energy than are the giant blue stars of the same visual absolute magnitude.

A further point of interest arises from the close relation between a star's spectrum and the transmission of its radiation through a water-screen. When more radiation is lost in passing through the screen than is normal with the spectral class to which a star belongs, this has been traced to the presence of a dark companion to the star which makes its presence known in yet a new way by the action of its hitherto unnoticed infra red radiation. It is to be hoped that the method may be made more sensitive, or that some more sensitive measure of infra-red radiation may be developed which will enable the astronomer of the next century to measure the radiation from the dark nebulae and—it is not an impossible thought—to [illegible] the dark stars on the next *Carte du Ciel*.

University and Educational Intelligence.

BIRMINGHAM.—The following appointments have been made: Assistant Professor K. N. Moss to be professor of coal and metal mining; Prof. G. Haswell Wilson to be professor of pathology in succession to Prof. Shaw Dunn; and Mr. T. H. P. Veal to be assistant lecturer in civil engineering.

CAMBRIDGE.—The Chancellor of the University has appointed Prof. H. R. Dean, professor of pathology in the University of Manchester, to be professor of pathology in succession to the late Sir German Sims Woodhead.

THE Salters' Institute of Industrial Chemistry has awarded fellowships for post-graduate study to Messrs. C. G. Harris, W. S. Martin, J. H. Oliver, and W. Randerson, and has renewed the fellowship of Mr. F. R. Jones.

A PROSPECTUS has been issued from the chemistry department of the Borough Polytechnic Institute, Borough Road, S.E.1, for the coming session. In addition to the customary course in general and organic chemistry, electro-chemistry, and the chemical technology of the essential oils, a grouped series of courses have been arranged, for this session, to meet the needs of students taking the National Certificate in Chemistry. There will also be a series of lectures on the chemistry of foodstuffs and a course on chemistry as applied to the laundry industry. In assessing the fees payable by students, special consideration is given to apprentices, while there is a special scale for students residing outside the county of London.

THE convenient practice of issuing abridged and sectional calendars adopted by the authorities of Battersea Polytechnic, Battersea Park Road, S.W.11, has been continued for the coming session. The abridged calendar of afternoon and evening classes gives some idea of the scope of the institution's activities; courses are provided in mechanical, civil, and electrical engineering, pure and applied mathematics, physics, chemistry and technological chemistry, hygiene, photography, and domestic science. The fees are fixed for students residing in the London area while at the Polytechnic, but for those residing outside the county an additional fee, generally equivalent to the difference between the ordinary school fee and the cost to the London County Council of the student's education, is charged.

IT is announced in *Science* that Prof. A. Sommerfeld, of the chair of mathematical physics at the University of Munich, will be in residence at the University of Wisconsin for the first part of the academic year 1922–23, holding the Karl Schurz memorial professorship in the university for that period. The Karl Schurz memorial professorship was founded in 1910 in memory of Karl Schurz, of Watertown, Wisconsin, sometime member of the board of regents of the State University, as an exchange professorship with the German universities, and the appointment of Prof. Sommerfeld marks the resumption of the professorship after the interruption caused by the war. Prof. Sommerfeld is expected to lecture on atomic structure, and on either the analysis of wave propagation or the general theory of relativity.

Calendar of Industrial Pioneers.

September 10, 18[illegible]. George Medhurst was buried.—The projector of the atmospheric railway, of which he published descriptions in 1812 and 1827, Medhurst was born in 1759, began life as a clockmaker, and was afterwards a machinist in Soho. Various atmospheric railways were constructed, but not till some years after Medhurst's death.

September 12, 1870. Karl August Steinheil died.—Born in Alsace in 1801, Steinheil in 1835 became a professor in Munich, where he invented a form of electric telegraph. During 1849–1852 he was director of the Department of Telegraphs at Vienna, while three years later he founded an optical institute at Munich.

September 12, 1914. Edward Riley died.—Riley's name is associated with two great advances in the manufacture of steel. As a young chemist at the Dowlais Iron Works in 1857 he made experiments on the Bessemer process, while some twenty years later, as a consulting chemist he was associated with Thomas and Gilchrist in the introduction of basic linings in converters. He was also a pioneer in the accurate analysis of iron and steel.

September 13, 1906. Hubert Henry Grenfell died.—A pioneer in the development in modern gunnery, Grenfell, when first lieutenant of H.M.S. *Excellent* in 1869, with Chief Engineer Edward Newman, worked out the first design of hydraulic mounting for naval ordnance. Retiring in 1886 he joined Armstrong's of Elswick, and in 1891 invented self-illuminated sights for night firing.

September 14, 1882. Georges Leclanché died.—An inventor who by a single invention won a world-wide reputation, Leclanché was for some years chemical engineer in the laboratory of the Chemin de Fer de l'Est. His well-known battery was patented in 1867.

September 14, 1892. Rudolph Proell died.—Trained at the Technical Academy in Berlin, Proell became a professor in the Technical High School at Aix-la-Chapelle, but afterwards as a consulting engineer devoted himself to the development of automatic valve gears.

September 14, 1907. Leveson Francis Vernon-Harcourt died.—Educated at Harrow and Balliol College, Oxford, Vernon-Harcourt, after graduating in 1862, became a pupil of Sir John Hawshaw. From 1882 to 1905 he was professor of civil engineering in University College, London, and was widely known as an authority on all that concerns tidal harbours, rivers and estuaries. In 1895 he served as president of the Mechanical Science Section of the British Association.

September 15, 1859. Isambard Kingdom Brunel died.—Among the engineers of the first half of the nineteenth century Brunel holds a high place. He assisted his father on the construction of the Thames Tunnel, became engineer to the Great Western Railway, introduced the broad gauge, and was the designer of the Clifton Suspension Bridge and the Albert Bridge at Saltash. With his three ships, the *Great Western*, 1838, *Great Britain*, 1843, and *Great Eastern*, 1857, he made notable contributions to the advancement of naval architecture. He is commemorated by a window in Westminster Abbey.

September 16, 1871. Dennis Hart Mahan died.—For forty years Mahan was professor of civil and military engineering at the Military Academy, West Point, and published works on these subjects, his course of civil engineering being translated into various foreign languages. He was one of the incorporators of the American National Academy of Science.

The Progress of State Afforestation.

THE Geddes Committee recommended the abolition of the Forestry Commission, and the discontinuance of the scheme of State afforestation that was sanctioned by Parliament in 1919 Fortunately these drastic measures were not adopted by the Government. The Treasury, however, has now restricted the Commissioners' operations, by reducing considerably the annual instalment from the forestry fund, which had been fixed at 350,000*l*. In consequence, the forestry staff has been greatly reduced, all purchase of land for the purpose of afforestation is suspended, and planting operations are greatly curtailed. It is discouraging to be aware of these facts, while reading the second annual report [1] of the Forestry Commissioners, which is a record of continuous progress till the end of September 1921

The report shows unexpected ease in the acquisition of suitable land for planting trees In order to reduce current expenditure to a minimum, the policy has been pursued of leasing as much and buying as little land as possible. In September 1921 the Commissioners were actually in possession of 68,489 acres of "plantable land," of which two-thirds had been leased at a rent of about 2*s*. per acre, and one-third purchased at the low price of 1*l*. 8*s*. per acre The afforestation of cheap land like this adds materially to the real wealth of the country, as the timber produced will be much more valuable than the poor grass, rushes, bracken, furze, and heather which now cover the ground

Afforestation also provides a ready means of giving work to the unemployed during seasons of bad trade. In November last, 250,000*l* was allotted to forestry from the Unemployment Fund, and in spite of the difficulty of organising and in many cases improvising forestry operations with unskilled labour, more than 4000 men were set to work Landowners and corporations were induced to plant, by small grants which were unencumbered by any condition except that unemployed labour should be utilised. As a result about 11 000 acres were planted on private estates, and preparation was made for the planting of a further 11,500 acres in subsequent years, a notable addition to the woodland area of Great Britain

The actual work of afforestation on the lands acquired by the Commissioners was restricted in the first year by the lack of young trees; but 7794 acres had been planted by the end of the second season. Large quantities of tree-seeds were imported and extensive nurseries established at convenient centres, the latter covering in September 1921 an area of 607 acres and carrying a stock of 111 million seedlings and 33 million

[1] Second Annual Report of the Forestry Commissioners: Year ending Sept 30, 1921. (London. H M. Stationery Office, 1922) 1*s* net

transplants. The report gives detailed information in tabular form about the area, cost, and species of the various plantations and nurseries. The positions of the different State Forests and Crown Woods are indicated in a sketch map.

Four schools for apprentice woodmen have been established, where sixty men received training in 1920–1921. These are situated at Parkend in the Forest of Dean, Burley in the New Forest, Chopwell in Durham, and Beauly in Inverness-shire. Research was carried on by six members of the Commissioners' staff; experiments were made on the germination of seeds; on the protection of seed-beds from drought, frost, and weeds; on insect pests; and on planting procedure. Seventy-nine sample plots, scattered over England, Wales, and Scotland, were under observation in September 1921. These plots will be thinned and measured periodically, in order to provide data as to the rate of growth and the best methods of thinning plantations of the different species.

The report concludes with an interesting account of the drought of 1921. It caused great damage in England and Wales, the death-rate among newly planted trees being 35 per cent. It is satisfactory to note that the Commission's plantations formed in the previous year did not suffer to any appreciable extent.

The Green Flash at Sunset.

The "Green Ray" or "Green Flash" (Rayon Vert) at Rising and Setting of the Sun. By Prof. Dr. M. E. Mulder. Pp 141 (London: T. Fisher Unwin, Ltd., 1922.) 6s. net.

WHEN the sun sets behind a distant and clear horizon, its last rays disappear with an emerald green flash. The coloration is due to the refraction of light in our atmosphere by which the sun's image is raised through about half a degree, the elevation increasing from the red to the violet end of the spectrum. As the violet and -to some extent—the blue rays are absorbed by the layer of air through which the light has to pass, it is the bluish-green part of the spectrum that is dominant at the ultimate moment of sunset. This seems clear enough and even obvious. But there are always certain minds that distrust the obvious—not always to the disadvantage of science—and others which rebel against a commonplace explanation of a striking effect. Imagination is always ready to supply more or less fanciful alternatives leading to controversies and correspondence in scientific journals.

In this manner a considerable amount of literature on the "green flash" has accumulated, and this is now collected by Prof. Mulder in a volume of 140 pages. The book is readable and interesting. But the interest is mainly psychological, depending on the descriptions by which observers record their impressions and on their knowledge of the conditions under which the green flash appears. The two serious alternative explanations that have been offered to replace the one based on the dispersion of light in our atmosphere might be dismissed in one sentence. The green flash cannot be the after-image in an eye fatigued by the red light of the sun, because it appears at sunrise, as well as at sunset, nor can it derive its colour from actual passage through the sea, because it is also seen when the sun disappears behind a land horizon.

The author aims at giving us a complete account not only of everything that *can* be said on the subject, but of everything that *has* been said on it. We are told how observers have put their impressions into words and find transcriptions of a large part of the correspondence that has appeared in NATURE, in the Journal of the British Astronomical Association, in the *Meteorologische Zeitschrift*, and in other publications. The same arguments are repeated over and over again, until we feel that a horse dead and duly flogged had better be buried; this might save us from being worried by its ghosts and reincarnations.

Nevertheless, the account has its value as a chapter of scientific history. We note with interest that the first printed description of the green flash that can be traced is contained in a novel by Jules Verne entitled, "Le Rayon Vert," and published in 1882. Perhaps some readers of NATURE can verify the *Leit-Motif* of the story, taken apparently from a Scotch legend, according to which those who have once seen the green ray acquire the power of seeing what is in the hearts of others as well as in their own.

I first noticed the green flash in February 1875 on several successive mornings at sunrise while traversing the Indian ocean. The appearance was so striking and the explanation seemed so obvious that I took it for granted I had only witnessed a common and well-known phenomenon. In July 1878 during a passage to the United States I directed the attention of several members of an eclipse expedition to the appearance at sunset; among them was Mr. Cowper Ranyard, whose subsequent views on the subject are quoted with approval by Prof. Mulder. I still failed to realise that the effect had never received the attention of scientific men, though I understand that astronomers were familiar with the fact that the light of a star near the horizon is drawn out into a vertical spectrum.

If the author's investigation of the scientific literature is as exhaustive as it appears to be, the first scientific notice of the green flash was published only in 1885,

when Chevreuil communicated to the French Academy observations made in the Indian Ocean by Trèves, who adopted the erroneous theory of complementary colours. The reader must be referred to the book itself for the subsequent discussion. Some praise should be given to the author for the manner in which he keeps up the interest of his account and the fairness with which he recites the arguments of different writers. According to his own view a complete explanation is still wanting, although he agrees that it must be based on the dispersion theory. But I would suggest that his reservations depend almost entirely on the importance he attaches to discrepancies in the descriptions by different observers and in their estimates of the duration of the flash. Apart from real differences in atmospheric conditions that may be very considerable, it is not to be expected that men, not specially trained in such observations, could tell with any degree of certainty whether an outburst of light lasts a tenth of a second or two seconds. Some have described the flash as appearing in the form of a short line, while on others it has left no impression of shape. The author, who has been a professor of ophthalmology, is not likely to have forgotten the possible effects of astigmatism, but even a perfect eye might see a point of light drawn out into a vertical line if the eyelids have been partially closed to screen them from the glare of direct sunlight. When seen through a telescope the appearance seems to be much more regular, the green coloration first appearing at the corners of the cusp that remains above the horizon. There seems no reason to doubt that dispersion combined with absorption of light completely accounts for the effect.

Is it not time that the green flash should find its place in elementary text-books? It is eminently suitable for them, and only by this means shall we be saved from further discussions covering the same ground.

Arthur Schuster.

Village Communities.

The English Village: The Origin and Decay of its Community: An Anthropological Interpretation. By Harold Peake. Pp. 251. (London: Benn Bros., Ltd., 1922.) 15*s*. net.

SEEBOHM in 1883 issued his well-known work on the English village community, which he examined in its relation especially to the manorial system and to common field husbandry. Among the general conclusions of his work was the view that "neither the village nor the tribal community seems to have been introduced into Britain during a historical period reaching back for 2000 years at least; . . . the village community of the eastern districts of Britain was connected with a settled agriculture which, apparently dating earlier than the Roman invasion and improved during the Roman occupation, was carried on, at length, under the three-field form of the open-field system which became the shell of the English village community." Without following out the discussion of Seebohm's views it may be said that the accumulation of archæological evidence since his day has made far more probable his view that there were agricultural settlements on cleared forest lands in Britain well before Roman times. The mapping of the catalogued Iron-Age finds from the lists given in the report on the Glastonbury Lake Village would furnish presumptive evidence on this point. It is, however, clear that Seebohm attributed great importance to Roman influence, which he says "enforced the settlement and introduced . . . fixed rotation of crops" "within the old Roman provinces (N. of the Alps) and in the Suevic districts along their borders," the area of "the geographical distribution of the three-field system."

In Seebohm's work there are frequent indications of his feeling out towards what was then the almost uncharted background of pre-history. It is the great merit of Mr. Peake's work that he has used his rich archæological knowledge as well as his historical reading in order to reach back beyond Seebohm. His interest is not in any question of origins of manorial organisation, but rather in the attempt to make the much-needed link between archæology and documentary studies for Britain. That this is one of the prime needs of our time admits of no question, and it is advisable that specialists on both sides should treat with special consideration pioneers who, like Mr. Peake, are trying to find the much-needed links.

For Mr. Peake the germ of the village community is to be found among the Neolithic agriculturists of the Swiss and Alemannic and Bavarian regions north of the Alps and is a social characteristic of the dark, broad-headed Alpine Race in those areas. He also suggests their domination by Nordic men of the Bronze Sword, but leaves the fuller working out of this subject to a companion-book to be issued shortly. These warriors set out about 1200 B.C. to dominate a large part of Europe and reached Britain within less than a century, as there is but very little difference in the types of sword found along their routes. Their followers were cultivators, and from evidence of bronze-sickles, of ploughs as substitutes for hoes, and of bronze axes in plenty, some late ones of which undoubtedly tell of forest-clearing, Mr. Peake believes they spread, at any rate, the germs of the village community in cleared forest areas. The landing of these people at Chelsea and Brentford as well as up the East Anglian Ouse

gives a clue to their access to the parts of England where the three-field system is best shown. That they did not at once dominate the west is clear from archæological evidence, especially from the finding of rapier-like dirks in place of leaf-shaped swords in the south and south-west. In Wales and other hill-lands the moorland-village seems to have survived, and, when valley clearing spread there, family groups in single households moved downhill and built the Tyddyn near shelves of cultivation on the hill-sides. Mr. Peake thinks the Romans met the valley-village-community in Gaul and Alemannia and probably interfered with it as little as possible, so that according to him, the continuity from earlier times would be much greater than Seebohm thought This is a view which obviously needs further examination on the basis of study of geographical distributions and we specially need maps of the distribution of open-field villages in France. Mr. Peake's view is, at any rate, far more helpful than the one which would ascribe the three-field system to the Saxon invaders of Britain, for these last came from a region where the one field scheme was characteristic and they had little connexion with the Alemannic areas of distribution of the three-field system

Having outlined this interesting opinion Mr. Peake follows, on fairly orthodox lines, the open-field valley-village down to its decay He accepts the general view that diminution of fertility of the land was a factor of this decay, though that is now disputed and it is thought that the properly-organised folding of stock pastured on uncultivated lands would bring in enough manure. That this organisation was adequately maintained everywhere in view of competing claims for the manure between lord and tenant is, however very doubtful, so the view in this book is probably not very far from correct

Mr. Peake's years of public work in rural England give a special interest to his concluding chapter, which asks, what of the future? He sees that the old village is dead or dying from loss of internal cohesion and that there is too much tendency towards occupational as against neighbourly cohesion He also fears the further urbanising of the people if the Garden City idea, which he admits to be the best urbanism, spreads. He thinks the Saxon village may have had less than 100 people, the mediæval village perhaps nearly 200, the modern survival about 200, more or less. As civilisation developed in classical lands villages fused, and there is, according to Mr. Peake, much need of larger units, especially for shopping and amenity purposes. The village has been losing its people, especially the best, at an alarming rate, but the tide of numbers turned a little after 1900 in several districts, thanks probably to the motor car and cycle. To redeem village life from dulness Mr. Peake thinks a population of about 1000 would be desirable, and that in such a unit most standard occupations could be represented, an important factor of contentment now commerce has enlarged our needs. He pleads for farm buildings around the outskirts of the village so that the labourer may be near his beasts, and for small holdings in the outer ring of the village. A village of 1000 can have a doctor, a lawyer, a bank, a bootmaker, a builder, a carpenter, a reasonable school, a public hall, and a few shops of some value. Such villages would encourage retired people, maiden ladies without specialised occupation, and so on to settle in them, and might well lead to a redevelopment of handicraft at all events in leisure time

The detailed suggestions may raise dispute, but what is of value here, besides the long and intimate working-experience of rural life which the author possesses, is the fact that the present unfortunate tendency towards separatist specialism is avoided. It is seen that small holdings *per se* are not enough, and that the settling of wage rates or drafting of housing schemes is only a partial help. It is Mr. Peake's desire to start from life, and from the provision of opportunities of healthy exercise of varied faculties, that marks out his book as worthy of careful and earnest consideration. H. J. F.

Climbing Palms and the Sago Palms.

Annals of the Royal Botanic Garden, Calcutta Vol 12 Part 2. *Asiatic Palms Lepidocaryeæ*. Part 3 *The Species of the Genera: Ceratolobus, Calospatha, Plectocomia, Plectocomiopsis, Myrialepis, Zalacca, Pigafetta, Korthalsia, Metroxylon, Eugeissona* By Dr Odoardo Beccari. Text, pp. vi+231+6 plates. Plates, 120, size 21 in × 14 in. (Calcutta Bengal Secretariat Book Depot, 1918–1921.) Rupees 40; 3*l*

IT is a matter of great regret that the late Prof. Beccari did not live to see the publication of the final part of his fine memoir on the Asiatic Lepidocaryeæ, which he had very fittingly dedicated to the memory of the late Sir George King, the founder of the Annals of the Calcutta Botanic Garden.

It was characteristic of Sir George that he selected the proper people to prepare the valuable memoirs that have preceded the one under review, though his own contributions are among the most noteworthy of the series. This present part constitutes the third of Prof. Beccari's memoirs on the Lepidocaryeæ, vol. xi. having been devoted to the important genus Calamus, and vol. xii., part 1, to the genus Dæmonorops. Like

its predecessors, the present part is accompanied by a magnificent series of plates and analytical figures of the flowers and fruits of the various species, which very materially enhance the value of the memoir.

The genus Ceratolobus, which is confined to the Malay Peninsula, Sumatra, Java and Borneo, consists of six species, four of which are described by Beccari. Three of these four are found in Borneo and two in the Malay Peninsula—one of the later, *C. lævigatus*, Becc. having six varietal forms spread over the Malay Peninsula, Sumatra and Borneo. *Calospatha Scortechinii*, collected by that assiduous botanist, Father Scortechini, in Perak, and described by Beccari, comes next on the list and is an interesting and very distinct palm, having a homogeneous albumen in the seeds, two to three in a fruit. In the genus Plectocomia, which are large, spinous, calamoid palms with terminal inflorescences, six new species are described. One of these, *P. Kerrana*, was discovered at Doi Soetep, near Chiengmai, Siam, by Dr. Kerr, who has made known to us the riches of the Siamese flora by his admirable collections in that country.

Plectocomiopsis is a new genus described by Beccari, containing five species, from Lower Burma and throughout the Malay Peninsula and Sumatra, and is again a calamoid, diœcious genus allied to Myrialepis, Becc. In its vegetative organs it resembles Plectocomia, though it differs widely in the spadices and flowers. Beccari then passes to the genus Zalacca, a characteristic and exclusively Indo-Malayan group containing thirteen species, denizens of rich, deep and moist soil in the recesses of primæval forests. The home of *Z. edulis*, which is frequently cultivated for its edible acid fruits, is not definitely known, but it is considered to be a native of the Malay Islands. It has been known since the time of Clusius, who examined fruits of this palm sent over from Bali in brine about 1600. Two new varieties of this species are described, and six new species by Beccari; of the latter, *Z. dubia* is only certainly known from the male flowers.

The genus Pigafetta described by Beccari was regarded by Martius as a section of Metroxylon, the sago palm, but Beccari proves that it is a distinct genus by its polycarpic nature. It is not closely allied to any other genus of Lepidocaryeæ, and is a tall tree with diœcious, axillary spadices and small calamoid fruits. It is due to these small fruits, no doubt, which are eaten by birds, that this palm, *P. filaris*, has so wide a range in the Moluccas, Celebes, New Guinea and Indo-China.

The next genus dealt with, Korthalsia, is again a genus of climbing palms containing twenty-six species, mainly Malayan. They are of economic use as, being very tough, the naked canes are used for tying, etc., by the natives; they are also of interest in being myrmecophilous, with the appendage at the mouth of the leaf sheath (the ocrea) largely developed and sometimes transformed into a closed ant nidus. Extra-floral nectaries are also developed in the axillæ of the leaflets.

Metroxylon, the sago palm, and Eugeissona, one species of which, *E. utilis*, Becc., also yields a sago flour, complete the Asiatic Lepidocaryeæ, and the part is concluded with an enumeration of the extra Asiatic palms belonging to this family, among which Raphia and Mauritia are perhaps the best-known genera.

The genus Metroxylon contains six species with numerous varieties, and the account of these valuable palms occupies nearly forty pages of the memoir. They are arborescent palms with a terminal inflorescence, and the two best-known species are *M. Rumphii* and *M. Sagus*, which are widely cultivated in the Moluccas, for the sake of the starch or sago flour extracted from the stem. Both these palms yield many other commodities used by the natives. Prof Beccari considers the Moluccas to be the home of these two species, and especially the island of Ceram, where a new species, *M. squarrosum*, Becc., has been found in abundance at the east end. Owing to their importance in affording food to the natives, they have now been carried far and wide.

To appreciate the value of this work it must be studied in detail, and all students of palms and botanists generally will realise how much they have lost by the death of Prof. Beccari, who was the pre-eminent authority on palms. A. W. H.

The Control of Electric Power.

Switching Equipment for Power Control. By S. Q. Hayes. Pp. vii+463. (New York and London: McGraw-Hill Book Co., Inc., 1921.) 20*s*.

SOME of the most important problems with which the engineer of a large power station has to deal are in connexion with the switches and control apparatus of his distribution system. Information on this subject can be found in a very condensed form in several text-books, but there is a demand for more detailed information, and in particular there is a great demand for a definite statement of the physical principles on which many of these devices are supposed to act. In Mr. S. Q. Hayes' book detailed information is given of many types of switchgear of American manufacture, but as a rule the descriptions are similar to the descriptions we get in manufacturers' catalogues, and in some cases they are actually taken directly from these catalogues. The author is one of the leading experts on switchgear, and occasionally

the reader is gratified by a brief description of the theory on which the device is founded, but in many cases no hint is given.

In our opinion the value of the book would be very greatly increased by additional brief descriptions of the physical laws which govern the action of many of the devices used by engineers. For example, a table of the rating factors by which the voltage of a given circuit breaker must be multiplied so as to get its rating at various heights above the sea level is given. It would be useful to give the theory used by the General Electric Company of America in getting these numbers.

Many types of the spark gaps used in practice are given, and it is pointed out that the sphere gap has a greater speed of discharge than the horn gap. The "impulse gap," which we believe was perfected during the war in connexion with the spark gap used in the magneto circuit of an aeroplane, is now adopted for lightning arresters. The Westinghouse Company state that it is more efficient than any other spark gap. An investigation of the action of the lightning arresters described would be a very promising field of research for the pure physicist.

In reading this book one gets accustomed to the American words "resistor" and "reactor" which are used for "resistance" and "reactance coil" respectively, and these words might well be adopted in this country. Electrical engineers talked about "omnibus bars" thirty years ago, it then became "bus bars," and now apparently it has become "busses." This book will be useful to the switchgear expert. A. R.

A Modern Text-book of Chemistry.

Inorganic Chemistry. By Prof. T. M. Lowry. Pp. xi+943. (London: Macmillan and Co., Ltd., 1922.) 28*s.* net.

FIFTY years ago there were no books on physical chemistry. The work which had been done on the borderline of physics and chemistry was scattered in different journals and was not readily accessible to the student. The first volume of Miller's "Chemistry," Tilden's "Chemical Philosophy," and certain articles of the old Watts's "Dictionary" were the first available summaries of what is now one of the most important branches of the subject. The works of Lothar Meyer and Ostwald, published in the late 'seventies of the last century, did much to direct attention to the importance of physical chemistry. The first professor of physical chemistry was appointed only twenty-five years ago, and even now this branch of the subject is still allotted to a lecturer at some of the universities in this country.

It is now recognised that inorganic and organic chemistry will become a mere record of facts, the interpretation of which, without the aid of physical chemistry, will remain undisclosed. It is therefore a matter of congratulation to the publishers that they should have been able to arrange for the publication of a book on inorganic chemistry by a physical chemist. The author is also to be congratulated on the way in which he has fulfilled his task. Perhaps the severest test of such a book is to refer to all the parts of the work which one knows are stumbling-blocks to the ordinary intelligent student. Prof. Lowry's book stands this test remarkably well; in one case alone, the liquefaction of gases, will the information need to be supplemented by the teacher. If it had been possible to give the references to original papers the book would have sufficed for any chemist who was not intending to devote himself to inorganic chemistry as his main subject, although the author in his preface seems to disclaim the use of his book as a book of reference.

The book is admirably produced, and the illustrations are remarkable, no less for their number than for their clearness. The book may be heartily recommended. H. B. BAKER.

Our Bookshelf.

Drahtloser Übersee-Verkehr. Von Dr. Gustav Eichhorn. Pp. 69+xx. (Zurich: Beer et Cie, 1921.) 7 francs.

IN the first two chapters of the publication under notice, an excellent description is given of the great German radio-station at Nauen and of the receiving station at Geltow, twenty miles south of it. The third chapter discusses the theory of thermionic tubes, and the method of indicating the paths of the various currents by marking them in different colours is to be commended. The last chapter on radio-telephony is concerned mainly with modern German practice. In the Appendix a few well-known papers by Howe, Vallauri, etc., are published. The book is clearly printed, and the photographs of the Nauen station and the great lattice towers with their net-works of wires show on what a huge scale it is designed.

During the last few years the station has been practically redesigned. The standard system of transmission does not yet seem to have developed. For example, they are at present constructing seven new towers, each 210 metres high, to enable them to communicate with Argentina. Under favourable atmospheric conditions the Telefunken Co., who own the station, have maintained communication with Japan for several years, although the messages have to go overland across Europe and Asia. The antennæ can be separated into four separate sections, each of which can be attached to a separate transmitter. When weather conditions are adverse all the antennæ can be connected in parallel. They then have a joint capacity of 0·01 microfarad. The two largest sections are each

connected with 400 kw. high-frequency alternators through two or three frequency doublers connected in cascade. The smaller sections are connected to smaller machines. Although the antennæ are close they can be operated quite independently of one another.

Dr. Meissner, the engineer-in-chief, hopes to reduce the earth-resistance of the antennæ to a fraction of its present value. How much this resistance lowers the efficiency can readily be seen by the figures given in this book. For example, in one case the effective current in the antennæ is given as 360 amperes and its resistance is 2·7 ohms. We learn that radio-telephonic systems are now established between Munich and Frankfort and between Berlin and Hamburg.

Phytopaläontologie und Geologie. Von Prof. Dr. W. Deecke. Pp. iii + 97. (Berlin: Gebrüder Borntraeger, 1922). 6*s*. 3*d*.

PROF. DEECKE's essays on broad questions of geology always provide interesting reading. The present work is perhaps unduly sceptical; but its stimulus to further comparison and correlation is based on careful reasoning. While mention is made of the importance of plants as rock-formers, the main thesis is their value for geologists as indicating topographic and climatic conditions in the past. The author shows how vegetation growing on cold uplands may become entombed in the downwash from mountain-sides, and he strongly opposes the notion that the flora of a sheltered Miocene marsh at Œningen may be used as an illustration of the contemporaneous flora on the Swabian Alb. Even the beautiful theory that the occurrence of rings of growth in fossil trees indicates an orderly recurrence of seasons, while their absence indicates a uniform climate, comes in for useful criticism. Though the author states the importance of calcareous algæ in forming Carboniferous limestones and, aided by their magnesium, Triassic dolomites, we miss a reference to the Cryptozoon question. This is a mere petrographic detail in the general discussion, which leaves us with the impression that geology, including the determination of local conditions of plant-growth, may be of more service to palæophylology than phytopalæontology can be to geology. G. A. J. C.

Practical Mathematics. By A. Dakin. Part I. (Mathematical Series for Schools and Colleges.) Pp. viii + 362 + 10 + xxiv. (London: G. Bell and Sons, Ltd., 1921.) 5*s*.

THERE should be a considerable demand for Mr. Dakin's book, as it contains just the sort of mathematics that is required by those who have to learn some elementary mathematical processes for practical use: decimals, mensuration and a few other topics in arithmetic, algebraic formulæ and equations, graphical methods, the geometry of rectilinear figures, similar figures, the circle and the sphere, with some numerical trigonometry. The treatment is very pleasant, and the student who uses the book will certainly fail to experience the aridity that the popular mind associates with mathematics. Mr. Dakin's account of graphs is particularly good; the introductory portion with the comparison and correlation graphs cannot but grip the student's interest, and make him feel that the method of graphs is worth acquiring. Historical notes are incorporated in the main text, and occasionally they are worked in very skilfully. Presumably the tables are given the title "logarithmic tables" from force of habit: they contain only natural trigonometrical ratios.

If the second part maintains the high standard of the present volume, the author will have added a valuable treatise to available books on the subject. It is to be hoped it will not suffer the fate of so many sequels. S. B.

Cours complet de mathématiques spéciales. Par Prof. J. Haag. Tome 2, Géométrie. Pp. viii + 661. (Paris: Gauthier-Villars et Cie, 1921.) 65 francs.

THIS is the second part of Prof. Haag's complete treatise on pure mathematics as required by the ordinary student specialising in mathematics. The first part dealt with algebra and analysis: the present volume is geometrical in the widest sense. We thus have analytical and synthetic geometry in two and in three dimensions, all treated simultaneously. A correct description of the book is therefore to call it a compendium of modern methods in geometry; it contains a vast amount of information of a fundamental character, and makes excellent reading.

Contrary to usual practice, especially in this country, the author does not devote very much space to conics as such. Perhaps he is right in thinking that the general practice of making a long and detailed study of the curves of the second degree tends to endow them with an importance that their practical usefulness does not justify. On the other hand the methods of the calculus are used freely.

Exercises in illustration of the principles and methods are conspicuously scarce, and no examples are given for the student to work. One is led to wonder whether a student can derive any considerable benefit from reading mathematics like a novel.

The Foundations of Æsthetics. By C. K. Ogden, I. A. Richards, and James Wood. Pp. 95 + pl. I-XV. (London: G. Allen and Unwin, Ltd., 1922.) 7*s*. 6*d*. net.

THE aim of the authors of this short treatise on æsthetics, as stated by themselves, is to present in a condensed form the greater part of accredited opinion on the subject while relating it to the main positions of the theory of art criticism. The various theories are not brought into opposition, but are distinguished to allow to each its separate sphere of validity. Beauty is thus discussed as intrinsic, in relation to the medium, to mysticism, and to its social effects and the like. They themselves find the solution of the problem in synæsthesis, a term covering a state of equilibrium and harmony in which the percipient becomes more fully himself and at the same time is in sympathetic understanding with other personalities. Hence arises the educative value of art. This theory is acceptable so far as it goes, but, like much of the current theory of æsthetics, in describing the "how" it fails to answer the question "why," a matter in which the anthropologist, censured by the authors, may be able to assist, in view of the current vogue of non-European art.

Cancer of the Breast and its Treatment. By Prof. W. Sampson Handley. Second edition. Pp. xvii+411. (London: Published for the Middlesex Hospital Press by J. Murray, 1922.) 30s. net.

IT is now more than six years since the exhaustion of the first edition of this book, in which Sampson Handley set out to place the operative treatment of cancer of the breast on a more rational basis by a closer study of the pathology of the disease. His main conclusions were: (1) that carcinoma spreads centrifugally by permeation of the lymphatic plexuses; (2) that reparative processes inadequate for cure are a normal part of the cancer process; (3) that inflammation and fibrous tissue formation are the principal of these defensive processes; (4) that invasion of the serous cavities is an event of critical importance in the process of dissemination; (5) that the embolic theory is only true for exceptional cases. The author instances much detailed evidence in support of these views, which have won widespread, though not universal, acceptance.

The present edition contains new chapters on radiological treatment, recurrence, Paget's disease of the nipple, lymphangioplasty, and injury as a causative factor in carcinoma. The book is well arranged and excellently illustrated.

A Handbook of Some South Indian Grasses. By Rai Bahadar K. Ranga Achariyar. Assisted by C. Tadulinga Mudaliyar. Pp. vi + 318. (Calcutta: Butterworth and Co., Ltd.; London: Constable and Co., Ltd., 1921.) 4 R. 8 As.

THIS book is intended to serve as a guide to the study of the grasses of the plains of South India for the use of officers of the Agricultural and Forest Departments and others interested in grasses. To remedy scarcity of fodder, foreign grasses and fodder plants have been imported, but so far none have been established on a large scale. The same amount of attention bestowed on indigenous grasses would have yielded better results. About one hundred grasses of wide distribution in the South Indian plains are described in this volume. The arrangement adopted is that of the "Flora of British India." Keys for the identification of genera and species are given, and good descriptions of each species are accompanied with figures of the whole plant and of the spikelet and details of the flower. The descriptions are preceded by a useful general account of the vegetative organs and flowers, and the histology of the stem and leaf. The figures, though not always quite sharp, are sufficiently clear to be a great help towards the identification of a given specimen. The handbook should prove of good service in South India.

The World About Us: A Study in Geographical Environment. By O. J. R. Howarth. Pp. 94. (London: Oxford University Press, 1922.) 2s 6d. net.

MR. HOWARTH has written a small book on a most important subject. Its size is the only fault we have to find with this excellent volume, although it is a pity that a title more descriptive of the content was not chosen. Enthusiasm for the geographical point of view too often leads to exaggerated statements of the influence of environment on human activities and is prone to encourage generalisations which not infrequently ignore the facts. Mr. Howarth is too careful a geographer to fall into these bad ways. He traces the nature of geographical influences, and in selected cases tries to estimate the forces of the factors involved. Chapters on the factors of environment are followed by others on distribution, migration, and transport. Particularly suggestive are the chapters on geographical environment and political states, and the local application of environmental study. The latter expounds the idea of regional survey in its value as a co-ordinating study of the things and peoples around us. Mr. Howarth's thoughtful and lucidly written volume should help geography to find its proper place in educational schemes. It deserves to be read widely.

Eyes and Spectacles. By Dr. M. von Rohr. Rendered into English by Dr. A. Harold Levy. Authorised translation. Pp. vi + 130 + xxii. (London: Hatton Press, Ltd., n.d.) 6s. net.

WE believe that this little book by Dr. Moritz von Rohr will prove as helpful to other English readers as it has been to the translator. Not only should it be read by those who prescribe and those who make lenses, but also by those who have to teach medical students or others the elementary principles on which the science of ophthalmology is based. The first part of the book deals with the eye itself, and also perspective as a form of perception by means of which the arrangement in space of the outer world becomes manifest to the observer. The most important section of the book deals with spectacles, and stress is laid on the two fundamental problems of increased clearness of vision and the alteration of direction of the object perceived. The final portion of the volume deals with spectacle frames. The translation, which has had the advantage of the author's revision, appears to have been carried out in an efficient manner.

The Link between the Practitioner and the Laboratory: A Guide to the Practitioner in his Relations with the Pathological Laboratory. By C. Fletcher and H. McLean. Pp. 91. (London: H. K. Lewis and Co., Ltd., 1920.) 4s. 6d. net.

THIS little book is for the guidance of the medical practitioner when he is obtaining the assistance of the laboratory. It enumerates clinical conditions with the appropriate pathological investigations, and gives clear instructions for the collection and transmission of the necessary material; there is also a brief résumé of vaccine and serum therapy. Attention to the details given will certainly assist the practitioner in supplying to the pathologist the right material in the right way.

Émile Coué: The Man and his Work. By Hugh MacNaughten. Pp. xi + 52. (London: Methuen and Co., Ltd., 1922.) 2s. net.

AN ambitious title appears on this book, which is really an enthusiastic appreciation of a doctor from whom the writer has received benefit. It records vividly scenes at Nancy, Eton, and London when Coué gave demonstrations of his methods. The writer gives a very charming impression of Coué as a man. The book is not, however, nor does it purport to be, a scientific treatise on Coué's theories of suggestion.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Capillarity.

IN Mr W B Hardy's excellent "Historical Notes upon Surface Energy and Forces of Short Range" in NATURE of March 23, vol 109, p. 375, he remarks that "the exact way in which the attractive forces act in causing the rise of fluid in capillary tubes and the spreading of fluid over solid and fluid surfaces is still obscure" He evidently rejects all explanations by any Laplacean conception of molecular attraction He probably holds that the explanation is to be sought in the modern electric theory of the constitution of matter, but that this theory has not as yet been developed far enough to throw sufficient light on the question. By the use of the term "attractive," however, he restricts the inquiry to a limited class of forces in terms of which these phenomena are to be explained. It is just possible that this restriction may preclude the solution of the problem

That it is possible to conceive of a force which cannot be put in this class of "attractive" forces of short range may be shown If a mass consisting of a single molecule exists at all, it has a position in ether-space at some particular instant It may be considered isolated from all other masses. There is, therefore, a closed boundary within which there are properties differing from those not within this boundary Any part of this closed boundary may be conceived as an area between space-regions called "mass" and "no-mass" If we say that *this enveloping area tends to become less*, we have defined a "force" which cannot be included in the class of attractive forces Further, if we say that, *when two such enclosures come into contact, the tendency to decrease does not exist in the area of contact*, since there is no distinction of properties on opposite sides of this area we have defined the law of the "force" for like masses Finally, if we say that *when the two masses are unlike there is this distinction of properties and, consequently, a tendency of the common area to decrease*, we have extended the law to unlike masses Space will not permit the elaboration of these conceptions

The question is: Does this "force" as conceived above really exist? Whether it does or not, repeated applications of the law as stated will account for surface tension of visible liquid and solid surfaces in terms of it It will be admitted that the phenomenon of coalescence of visible spheres of like liquids is a direct application of the law. Also, in his letter on "Cohesion" in NATURE of January 5 (vol 109, p 10), the present writer has shown experimentally that visible exterior cohesion and adhesion in solids and liquids may be accounted for by surface tension forces alone, and, consequently, may be explained by molecular (surface) tension Now these and even capillary-rise and fluid-spreading might conceivably be explained by intermolecular electric forces, though this has not yet been done, but it is difficult to see how the latent heat of a gas can be so accounted for, since in a gas the molecules are too widely separated to admit of short range intermolecular action at all, and the condensation of a gas, by which alone this great amount of heat is made available, is unattended by any chemical change or electrical effect. This latent heat, however, may be fully accounted for by molecular surface tension, as the writer has shown in the *Phil Mag.* v 41, p 877.

Either, then, the latent heat of a gas must be otherwise accounted for, or the existence of molecular surface tension must be admitted This in turn, it is true, may eventually be explained by the action of electric forces in the interior of the isolated molecule. In the meantime the writer offers the following explanation of capillary-rise and surface-spreading in terms of molecular tension as conceived above

The following phenomena are illustrative (*a*) If two free spheres of immiscible liquids be brought into contact, the mass of the one suddenly proceeds completely to envelop the mass of the other (*b*) If a free liquid sphere and a small solid which does not dissolve in the liquid be brought into contact, one of two actions takes place either the mass of the liquid forms a closed sheath about the solid, or the mass of the solid *tends* to envelop the liquid, but is prevented by internal cohesion from assuming the necessary form The liquid then stands out as a curved mound on the solid with a distinct "capillary" angle With water mercury acts as a solid metal It is on this differential action of this surface force of water

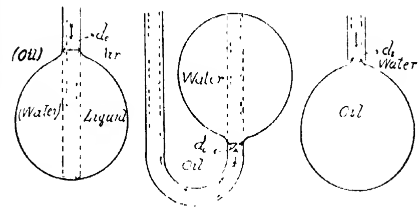

Fig 1 Fig 2 Fig 3

in union with those of small particles of minerals and rocks that the flotation processes for mineral separation depend

When a liquid is in contact with a solid, there are three areas in which this *tendency to decrease* exists in different degrees, namely, the liquid-air, the solid-air, and the solid-liquid areas, the sum of the latter two areas being constant At contact the only possible way in which these latter two tendencies can result in action is to decrease the solid-air area from its maximum by increasing the solid-liquid area from zero Experiments show (NATURE, *ibid*) that this change always proceeds to some extent In the case of water and rock it proceeds until *all* the solid-air area becomes solid-liquid area It does not reach this limit in the case of water and a mineral.

But the extent of this fluid-spreading depends further on (1) the tendency to decrease of the liquid-air area, unrestricted by internal cohesion, (2) the force of gravity acting on the liquid mass, (3) the form of the solid area, and (4) the amount of the liquid. Thus, a small drop of an oil such as oleic acid may not spread far on a horizontal glass surface, since the decrease in the glass-air area involves increases in both glass-oil and oil-air areas; whereas in capillary-rise this decrease does not involve any increase in oil-air area The oil will, therefore, ascend until its increasing weight balances the tendency to decrease (tension) in the glass-air area within the tube. Again, a hanging drop of the oil will completely envelop a large fragment of glass and hold it against its weight.

It is plain, then, that methods of measuring surface tensions of liquid-air and liquid-liquid areas should

be, so far as possible, free from errors arising from unknown changes in liquid-air areas and from the unknown solid-air and solid-liquid tensions. It will be seen that the capillary-rise method in reality does this, though there is difficulty in measuring the internal bore and keeping it clean. But the following arrangement seems to be as nearly as possible free from these objections, and to be adapted to measure the tensions of interfacial liquid surfaces as well.

The liquid (mercury excepted) is made to drop from a fine capillary tube having thin walls as in Fig. 1. In forming the drop, it spreads upward over the exterior surface and reaches a limiting size, shape, and position. It then slips down the tube at a uniform velocity with little modification in size or shape, and after suffering a slight check in its motion breaks its connexion and falls. We may then equate the whole tension about the tube with the weight of the drop, so that $T_{la} \times \pi d_e = W_L$ or $T_{la} = W_L/\pi d_e$, where T_{la} is the liquid-air tension and d_e is the external diameter of the tube.

The same drop formation occurs when the tube is arranged to drop water downwards in any lighter oil, or by a bent tube (Fig. 2) upwards in a heavier oil. In this case we have the equation $T_{wo} = \frac{W_w}{\pi d_e} \times \frac{\rho_w - \rho_o}{\rho_w}$, where the suffixes w, o, e, and i denote the words water, oil, external, and internal, and ρ is density, from which the tension of the water-oil surface may be calculated

On the contrary, when oil is dropped either downwards or upwards in water, it does not spread on any exterior water-glass surface, but forms its attachment as in Fig. 3. In this case we have $T_{wo} = \frac{W_o}{\pi d_i} \times \frac{\rho_w \sim \rho_o}{\rho_o}$.

These all give results agreeing with those recorded in the standard tables.

In accordance, then, with this conception of an elemental force not included in the class of "attractive" forces, we should expect that these changes in area would be always attended by a rise in temperature. If it be asked why the enveloping area about a free molecular mass tends to decrease, there is no answer; and neither is there an answer to the question as to why a large mass tends to approach another.

The Influence of Science.

THE seeming contradiction in my summary account of the case of Galileo (NATURE, August 5, p. 180), to which Sir Oliver Lodge directs attention in his letter (NATURE, August 26, p 277), needs an explanation. The great work of Copernicus (1543) was dedicated to a Pope, Paul III.; none of the Roman Congregations found any objection to it, and (Whewell, "History of the Inductive Sciences," I. 418, ed. 1847), says "lectures in support of the heliocentric doctrine were delivered in the ecclesiastical colleges." This was because of its being taught as a purely scientific doctrine.

Sir Oliver writes that Galileo "had endeavoured to get the Church to realise that the doctrine was not really antagonistic to Scripture when reasonably interpreted." This statement needs qualifying. Had Galileo contented himself with teaching the Copernican doctrine as a scientific hypothesis, he would not have been molested. But, being a fierce controversialist, he wanted to confound his many adversaries, the mathematicians, and the Aristotelians, by showing that Scripture was on his side (cp. Sir David Brewster, "Martyrs of Science," p. 58). Hence, disregarding the advice of the Bishop of Fermo "not to raise the question," and that, too, of many other ecclesiastical friends, among them Cardinals and Prelates, to the same effect, he demanded that "the Pope and the Holy Office *should declare the Copernican system to be founded on the Bible.*" *Hinc illae lacrymae.* On the other hand, the attitude of the Churchmen is well illustrated in a letter from Cardinal Bellarmine to the Carmelite friar, Foscarini, one of Galileo's friends, dated April 12, 1615. He writes: "If a true demonstration should be found that the Sun is placed at the centre of the world, and the Earth in the third heaven, and that the Sun does not turn round the Earth, but the latter round the former, then it will be necessary to proceed with great prudence in the explanation of Scripture, which seems to say the contrary, and rather to avow that we have not understood it, than to declare a demonstrated fact false." Astronomers had to wait until the discovery of aberration by Bradley before such a true demonstration was found.

Sir Oliver also writes that "Galileo was made to recant, to abjure, and curse the theory of the earth's motion." Whewell tells us (*loc. cit.*, p. 419), "He (Galileo) was accused before the Inquisition in 1615, but at that period the result was that he was merely recommended to confine himself to his mathematical reasonings upon the system, and to abstain from meddling with Scripture." After his contempt of court, in the second trial, of the year 1632, he was condemned as "vehemently suspected of heresy" He was sent to Arcetri, and had to recite a penance of certain prayers.

There was no implication in my former letter, as Sir Oliver writes, "that there was really no punishment, and that there was no call for anxiety and distress." The implication was that his troubles were largely, if not entirely, of his own seeking, and that his treatment was, according to the quotations I gave from Whewell, and from De Morgan, comparatively mild. I purposely quoted from non-Catholic writers, as they cannot be suspected of partiality towards the Roman Congregations. To these I add the testimony of Sir David Brewster (*loc. cit*, p. 88): "During the whole of the trial Galileo was treated with the most marked indulgence." Sir Oliver Lodge's quarrel is, therefore, with such eminent scientific men as Whewell, De Morgan, and Brewster (see also *op. cit*, p 77), to whom we may add Huxley, who ("Life and Letters," ii. 424) avowed that "the Pope and the Cardinals had rather the best of it"

But my chief implication was, and is, that the case of Galileo cannot fairly be considered as evidence of the hostility of the Church to natural science, and as a hindrance to her legitimate influence. Finally, I trust Sir Oliver Lodge will not think me discourteous in not treating of the other points raised in his letter, as I do not consider them to be relevant to the present discussion.

The Production of a Standard Source of Sound.

I HAVE recently had occasion to consider the problem of constructing a simple standard source of sound, and have been favourably impressed by the possibility of employing a "hot wire" grid—as used in the Tucker microphone (Phil. Trans A, vol. 221, pp. 389-430)—for this purpose. In this microphone the grid is made of fine platinum wire and heated by a current of 20-30 milliamperes. It is mounted in the orifice of a Helmholtz resonator, and when the latter is stimulated by a sound of suitable pitch, the vibration of the air in the orifice causes an increase

in the average rate of loss of heat by convection, and consequently there is a fall in the temperature, and hence in the resistance, of the grid. The fall in resistance can be measured by a Wheatstone bridge method. The way in which it is suggested that this process may be utilised in the construction of a standard source of sound is as follows. The source is made in the form of a cylindrical Helmholtz resonator—say from brass tubing about 2 in. diameter. At one end is fitted a telephone in such a way that the diaphragm forms part of the inner wall of the resonator, while at the other end is the orifice carrying the hot-wire grid. If the telephone diaphragm is made to vibrate by current from a thermionic valve oscillator, and the frequency of the current is adjusted until it is equal or nearly equal to that of the resonator, a pure tone of moderate intensity issues from the orifice. At the same time the hot-wire grid suffers a change of resistance which provides a measure of the amplitude of the vibration in the orifice, and hence of the *strength* of the source. With a standard pattern grid and holder the change in resistance is about 12 ohms when a sound of pitch 200 vibrations/sec. is produced, which is loud enough to be just audible at a distance of 10 feet—the source being placed on the ground in the open. The strength of the source can be varied at will by using a variable series resistance or a shunt with the telephone. The use of resonance serves to purify the note which comes from the telephone, but it is desirable in addition that the oscillator should be of such a type that the telephone note is already fairly pure. The use of a very impure note may lead to poor results, as the resistance change will then depend only partly on the amplitude of the fundamental.

It may be noted that a simple method is known of obtaining the relation between the change in resistance of a grid and the amplitude and frequency of the vibration producing it—the motion being simple harmonic. Hence, if the frequency of the vibration is known, the strength of the source (defined as the rate at which fluid is introduced or abstracted at the source) can be found in absolute measure. The amplitude of the waves—or, if preferred, the flux of energy—in the surrounding medium can then be calculated in certain cases. A simple case is when the source is close to a rigid plane.

Any other means of producing a suitable sound can be used in place of the telephone diaphragm provided it is small enough to go inside a resonator. If the damping factor of the resonator has been determined experimentally, the acoustical output of the primary source inside the resonator can be calculated from the indications of the hot-wire grid in the orifice. The output of the internal source includes (1) the radiation of acoustical energy from the orifice, which has been dealt with above, and (2) work done against viscous forces in the orifice. Unless the orifice is large, (2) is far the more important part, and the radiation losses may be negligible by comparison.

Occurrence of the Rare Whale, *Mesoplodon Layardi*, on the Tasmanian Coast.

SOME years ago, on July 30, 1918, my friend Mr. G. H. Smith of Leprena, Southern Tasmania, brought me word that a beaked whale, "without teeth," had been cast up on the beach at Recherche Bay near his property, that he had already removed the blubber, and that the carcase still remained on the shore. Being occupied at the time with university teaching I was unable to visit Recherche Bay till some weeks later. High seas were then running, and the remains had been lifted by these and thrown farther up on the basaltic boulders which strew the beach at this spot. This resulted in some considerable damage to the skeleton. Nearly all the ribs were broken, some into three or four pieces, and many of the neural spines had been smashed from the vertebrae. The skull was also damaged, although some of the flesh and integument was still adhering.

The body was naturally in a somewhat decayed and pulpy condition, but with Mr. Smith's help I was able to salve the remains and so obtain the skeleton. This is almost complete and is now in my Department.

My friend was good enough to hand me some measurements and notes which he had made and these I reproduce. The animal "was a female whale. The total length was about 18 ft., its jaws were 2 ft. 6 in. long, about 4 in. in diameter at the end, no teeth above the gums. Fins 2 ft. long, 8 in. wide, and tapered, not round like the black whale type. Its flukes were about 4 ft. wide; it had the appearance of a fast fish as it was rather thin in the body. There was a small fin on its hump, about a foot high, with a decided rake towards the tail. The colour the same as the sperm whale, dark grey and light underneath." Mr. Smith further states that the blubber yielded 50 gallons of oil of the finest quality, and that he believes that the animal was driven ashore by "killers," of which there were a number in the bay at the time. There were, however, no marks of injury on the body.

The matter of recording this specimen seems called for, particularly in view of the description by Mr. E. R. Waite, director of the South Australian Museum (Rec. S. Aus. Mus., vol. ii., No. 2), of the discovery, on the South Australian coast, of an immature male of this species of Mesoplodon. The Tasmanian specimen was a female and mature, as is witnessed by the condition of the skeleton and by the fact that the pulp cavity of the tooth is entirely closed below.

The form of the tooth corresponds exactly with that figured by Gray for his *Callidon güntheri* (Ann. Mag. Nat. Hist., 1871), which, as Flower and Turner suggested, was a female of the present species. It seems now that we must conclude from Waite's description that the mature condition of the tooth in the female represents a stage which is early passed through in the male.

No pelvic bones were discovered, nor was there any trace of the denticles found in the integument of the jaws of other species. The oil has a density of 0·88 at 12·5° C. This whale has now been recorded from the coast of every Australian State except Victoria and West Australia.

Atoms and Electrons.

ON the basis of any theory of atomic structure which classifies the elements according to rare gas type, cerium and thorium should be comparable with one another, since the atoms of each are possessed of four electrons more than those of the corresponding inert gases, xenon and niton respectively. There are, however, in the thorium atom, thirty-two more extra-nuclear electrons than in the cerium atom. In spite of this fact, it appears that *the distances between atomic centres in crystals of these elements are practically the same* (Ce = 3·62 A.U. and Th = 3·56 A.U., according to Hull), the distance being, if anything, slightly the

smaller for thorium Both crystallise in the face centred cubic lattice If the interatomic distances may be taken as representing atomic diameters, this means that in the same (or slightly less) volume there are concentrated in the thorium atom thirty-two more electrons than in the cerium atom, the total numbers in the two cases being, respectively, ninety and fifty-eight

Thorium is the next to the last element in the periodic table possessed of particular stability. Between the last, uranium, and neodymium in the preceding period, a structural relationship exists similar to that between thorium and cerium The crystal structures of these elements by the X-ray method have, unfortunately, not been worked out However, an approximate idea of the relative sizes of the atoms of these substances may be gained by a comparison of their atomic volumes According to Landolt-Bornstein's "Tabellen," the densities of neodymium and uranium are 6·96 and 18·7 respectively. Dividing the atomic weights (144·3 and 238·5 respectively) by these numbers gives for the atomic volume of neodymium 20·7, and for that of uranium 12·8 The corresponding quantities for cerium and thorium are about 20·5 each It thus appears that *in the atoms of uranium there are concentrated in about one-half the volume thirty-two more electrons than in the atoms of neodymium*, the total numbers of electrons being, respectively, ninety-two and sixty

It is perhaps significant in view of these facts that elements of higher atomic number than uranium are not known to exist, and that most of those of immediately lower atomic number are unstable With increasing nuclear charge the attractive forces exerted by the nucleus on the surrounding electrons concentrate the latter nearer and nearer toward the centre of the atom It does not appear improbable that the exceedingly powerful forces, both of attraction and repulsion, which must result from this concentration may be of sufficient magnitude to assist materially in bringing about those conditions of instability which result in radio-active disintegration If the large numbers of electrons in the atoms of the radio-active elements be conceived as rotating about the nucleus within the small space which the relatively small atomic volumes allot to the atoms of these elements, with orbits of different periods, there will evidently come times periodically when numbers of electrons in excess of the average will all be exerting attractive forces on the positive nucleus in the same direction In such circumstances it is conceivable that a positively charged constituent of the nucleus might be drawn out of its normal equilibrium position and, the local attractive forces which held it in its equilibrium position being overbalanced by the repulsive force between this new entity and the positive nucleus acting as a whole, be sent on its path as an α-particle The rate of decay of the atoms of the elements would then depend on the frequency with which this favourable configuration of electrons, which is just sufficient to exert the critical attractive force, occurred. The more stable the nucleus, the greater would the numbers of electrons all acting in the same direction need to be. But the greater the concentration required, the less frequently will it occur, other things being equal. Hence, for a more stable nucleus the rate of decay must be less. The rate of decay would thus depend primarily on the stability of the nucleus, and the mechanism suggested would constitute the trigger action by which the actual disintegration was brought about. The Freshwater Winkle.

I WAS, recently, fortunate enough to obtain a pair of the yellow-bodied variety of the freshwater winkle (*P. contecta*) from what I understand was the first consignment to be imported into this country Unfortunately the female died, and when I removed it from the aquarium the body fell out of the shell, the snail having apparently been dead a day or two. I then noticed that there was a row of five fully-formed baby snails—about ¼ inch in diameter—in the gelatinous egg-sac

Although I thought there was little possibility of their being alive, I released them with a pair of scissors and placed them in a saucer of water For twenty-four hours or so there was no sign of life, but, on the second day, I noticed that an operculum was forming on each and that the tentacled head of two of them had been extruded These were immediately placed in a well-established aquarium, and the following day the other three were similarly dealt with, they having also become active All are now feeding upon the confervæ on the sides of the tank and apparently doing well

I have never heard of such an experiment having met with success, and shall be glad to learn whether the result is new A. E HODGE.

The Effect of a Lead Salt on Lepidopterous Larvæ.

FOR some time we have been studying the effect of adding various metallic salts to the food of the larvæ of Lepidoptera, and, as the results will not be ready for publication for about a year, desire to direct attention to the surprising result of using a salt of lead When a dozen larvæ of *S ocellatus* were fed on sprigs of apple which had been treated with lead nitrate it was soon obvious that they were eating more freely and growing more rapidly than the controls; by the time they were about three-fourths grown they consumed double the daily ration eaten by the latter There was considerable disease among the controls and in another experimental batch, but those getting lead remained perfectly healthy and pupated about a fortnight earlier than the controls The pupæ were a very fine lot, the males weighing on the average about 15 per cent more than the controls, and the moths were large and somewhat peculiarly coloured, there were too few females for a comparison to be made Confirmatory results have been obtained with the larvæ of other moths

This curious result is not without parallel The herbage near the chimneys of lead-smelting works contains appreciable amounts of lead, and cases of lead poisoning have occurred among sheep; in Weardale, however, it is a common practice to pasture sheep as near as possible to these chimneys when they are being fattened, as the farmers consider that they fatten much more quickly than on other parts of the moors. HILDA GARRETT.

The Pigeon Tick.

THERE is a slight error in the statement of L. H. Matthews and A D. Hobson in NATURE of September 2, p 313, with regard to the latest previous record of the pigeon tick *Argas reflexus* In 1917 I secured four specimens from the tower of Canterbury Cathedral. At least two living specimens were forwarded to Mr. C. Warburton at the time.

The Cathedral receives a special cleaning every four years and *Argas reflexus* is invariably dislodged on these occasions. A. G. LOWNDES.

Marlborough College, September 4.

The Theory of Numbers.[1]

By Prof. G. H. Hardy, M.A., F.R.S.

I FIND myself to-day in the same embarrassing position in which a predecessor of mine at Oxford found himself at Bradford in 1875, the president of a Section, probably the largest and most heterogeneous in the Association, which is absorbed by a multitude of divergent professional interests, none of which agree with his or mine.

There are two courses possible in such circumstances. One is to take refuge, as Prof. Henry Smith did then, with visible reluctance, in a series of general propositions to which mathematicians, physicists, and astronomers may all be expected to return a polite assent. The importance of science and scientific method, the need for better organisation of scientific education and research, are all topics on which I could no doubt say something without undue strain either on my own honesty or on your credulity. That there is no finer education and discipline than natural science, that it is, as Dr. Campbell has said, "the noblest of the arts"; that the crowning achievements of science lie in those directions with which this Section is professionally concerned: all this I could say with complete sincerity, and, if I were the head of a deputation approaching a Government Department, I suppose that I would not shirk even so unprofitable a task.

It is unfortunate that these essential and edifying truths, important as it is that they should be repeated as loudly as possible from time to time, are, to the man whose interest in life lies in scientific work and not in propaganda, unexciting, and in fact quite intolerably dull. I could, if I chose, say all these things, but, even if I wanted to, I should scarcely increase your respect for mathematics and mathematicians by repeating to you what you have said yourselves, or read in the newspapers, a hundred times already. I shall say them all some day, the time will come when we shall none of us have anything more interesting to say. We need not anticipate our inevitable end.

I propose therefore to adopt the alternative course suggested by my predecessor, and try to say something to you about the one subject about which I have anything to say. It happens, by a fortunate accident, that the particular subject which I love the most, and which presents most of the problems which occupy my own researches, is by no means overwhelmingly recondite or obscure, and indeed is sharply distinguished from almost every other branch of pure mathematics, in that it makes a direct, popular, and almost irresistible appeal to the heart of the ordinary man.

There is, however, one preliminary remark which I cannot resist the temptation of making. The present is a particularly happy moment for a pure mathematician, since it has been marked by one of the greatest recorded triumphs of pure mathematics. This triumph is the work, as it happens, of a man who probably would not describe himself as a mathematician, but who has done more than any mathematician to vindicate the dignity of mathematics, and to put that obscure and perplexing construction, commonly described as "physical reality," in its proper place.

There is probably less difference between the methods of a physicist and a mathematician than is generally supposed. The most striking among them seems to me to be this, that the mathematician is in much more direct contact with reality. This may perhaps seem to you a paradox, since it is the physicist who deals with the subject-matter to which the epithet "real" is commonly applied. But a very little reflection will show that the "reality" of the physicist, whatever it may be (and it is extraordinarily difficult to say), has few or none of the attributes which common-sense instinctively marks as real. A chair may be a collection of whirling atoms, or an idea in the mind of God. It is not my business to suggest that one account of it is obviously more plausible than the other. Whatever the merits of either of them may be, neither draws its inspiration from the suggestions of common-sense.

Neither the philosophers, nor the physicists themselves, have ever put forward any very convincing account of what physical reality is, or of how the physicist passes, from the confused mass of fact or sensation with which he starts, to the construction of the objects which he classifies as real. We cannot be said, therefore, to know what the subject-matter of physics is; but this need not prevent us from understanding the task which a physicist is trying to perform. That, clearly, is to correlate the incoherent body of facts confronting him with some definite and orderly scheme of abstract relations, the kind of scheme, in short, which he can borrow only from mathematics.

A mathematician, on the other hand, fortunately for him, is not concerned with this physical reality at all. It is impossible to prove, by mathematical reasoning, any proposition whatsoever concerning the physical world, and only a mathematical crank would be likely now to imagine it his function to do so. There is plainly one way only of ascertaining the facts of experience, and that is by observation. It is not the business of a mathematician to suggest one view of the universe or another, but merely to supply the physicists with a collection of abstract schemes, which it is for them to select from, and to adopt or discard at their pleasure.

The most obvious example is to be found in the science of geometry. Mathematicians have constructed a very large number of different systems of geometry, Euclidean or non-Euclidean, of one, two, three, or any number of dimensions. All these systems are of complete and equal validity. They embody the results of mathematicians' observations of *their* reality, a reality far more intense and far more rigid than the dubious and elusive reality of physics. The old-fashioned geometry of Euclid, the entertaining seven-point geometry of Veblen, the space-times of Minkowski and Einstein, are all absolutely and equally real. When a mathematician has constructed, or, to be more accurate, when he has observed them, his professional interest in the matter ends. It may be the seven-point

[1] Presidential address delivered to Section A (Mathematics and Physics) of the British Association at Hull on Sept. 8.

geometry that fits the facts the best, for anything that mathematicians have to say. There may be three dimensions in this room and five next door. As a professional mathematician, I have no idea; I can only ask some competent physicist to instruct me in the facts.

The function of a mathematician, then, is simply to observe the facts about his own intricate system of reality, that astonishingly beautiful complex of logical relations which forms the subject-matter of his science, as if he were an explorer looking at a distant range of mountains, and to record the results of his observations in a series of maps, each of which is a branch of pure mathematics. Many of these maps have been completed, while in others, and these, naturally, are the most interesting, there are vast uncharted regions. Some, it seems, have some relevance to the structure of the physical world, while others have no such tangible application. Among them there is perhaps none quite so fascinating, with quite the same astonishing contrasts of sharp outline and mysterious shade, as that which constitutes the theory of numbers.

The number system of arithmetic is, as we know too well, not without its applications to the sensible world. The currency systems of Europe, for example, conform to it approximately; west of the Vistula, two and two make something approaching four. The practical applications of arithmetic, however, are tedious beyond words. One must probe a little deeper into the subject if one wishes to interest the ordinary man, whose taste in such matters is astonishingly correct, and who turns with joy from the routine of common life to anything strange and odd, like the fourth dimension, or imaginary time, or the theory of the representation of integers by sums of squares or cubes.

It is impossible for me to give you, in the time at my command, any general account of the problems of the theory of numbers, or of the progress that has been made towards their solution even during the last twenty years. I must adopt a much simpler method. I will merely state to you, with a few words of comment, three or four isolated questions, selected in a haphazard way. They are seemingly simple questions, and it is not necessary to be anything of a mathematician to understand them; and I have chosen them for no better reason than that I happen to be interested in them myself. There is no one of them to which I know the answer, nor, so far as I know, does any mathematician in the world; and there is no one of them, with one exception which I have included deliberately, the answer to which any one of us would not make almost any sacrifice to know.

1. *When is a number the sum of two cubes, and what is the number of its representations?* This is my first question, and first of all I will elucidate it by some examples. The numbers $2=1^3+1^3$ and $9=2^3+1^3$ are sums of two cubes, while 3 and 4 are not: it is exceptional for a number to be of this particular form. The number of cubes up to 1,000,000 is 100, and the number of numbers, up to this limit and of the form required, cannot exceed 10,000, one-hundredth of the whole. The density of the distribution of such numbers tends to zero as the numbers tend to infinity. Is there, I am asking, any simple criterion by which such numbers can be distinguished?

Again, 2 and 9 are sums of two cubes, and can be expressed in this form in one way only. There are numbers so expressible in a variety of different ways. The least such number is 1729, which is 12^3+1^3 and also 10^3+9^3. It is more difficult to find a number with *three* representations; the least such number is

$$175{,}959{,}000=560^3+70^3=552^3+198^3=525^3+315^3.$$

One number at any rate is known with *four* representations, namely,

$$19\times363510^3$$

(a number of 18 digits), but I am not prepared to assert that it is the least. No number has been calculated, so far as I know, with more than four, but theory, running ahead of computation, shows that numbers exist with five representations, or six, or any number.

A distinguished physicist has argued that the possible number of isotopes of an element is probably limited because, among the ninety or so elements at present under observation, there is none which has more isotopes than six. I dare not criticise a physicist in his own field; but the figures I have quoted may suggest to you that an arithmetical generalisation, based on a corresponding volume of evidence, would be more than a little rash.

There are similar questions, of course, for squares, but the answers to these were found long ago by Euler and by Gauss, and belong to the classical mathematics. Suppose, for simplicity of statement, that the number in question is *prime*. Then, if it is of the form $4m+1$, it is a sum of squares, and in one way only, while if it is of the form $4m+3$ it is not so expressible; and this simple rule may readily be generalised so as to apply to numbers of any form. But there is no similar solution for our actual problem, nor, I need scarcely say, for the analogous problems for fourth, fifth, or higher powers. The smallest number known to be expressible in two ways by two biquadrates is

$$635318657=158^4+59^4=134^4+133^4;$$

and I do not believe that any number is known expressible in three. Nor, to my knowledge, has the bare existence of such a number yet been proved. When we come to fifth powers, nothing is known at all. The field for future research is unlimited and practically untrodden.

2. I pass to another question, again about cubes, but of a somewhat different kind. *Is every large number* (every number, that is to say, from a definite point onwards) *the sum of five cubes?* This is another exceptionally difficult problem. It is known that every number, without exception, is the sum of nine cubes; two numbers, 23 (which is $2.2^3+7.1^3$) and 239, actually require so many. It seems that there are just fifteen numbers, the largest being 454, which need eight, and 121 numbers, the largest being 8042, which need seven; and the evidence suggests forcibly that the six-cube numbers also ultimately disappear. In a lecture which I delivered on this subject at Oxford I stated, on the authority of Dr. Ruckle, that there were two numbers, in the immediate neighbourhood of 1,000,000, which could not be resolved into fewer cubes than six; but Dr. A. E. Western has refuted this assertion by resolving each of them into five, and is of opinion,

I believe, that the six-cube numbers have disappeared entirely considerably before this point. It is conceivable that the five-cube numbers also disappear, but this, if it be so, is probably in depths where computation is helpless. The four-cube numbers must certainly persist for ever, for it is impossible that a number $9n+4$ or $9n+5$ should be the sum of three.

I need scarcely add that there is a similar problem for every higher power. For fourth powers the critical number is 16. There is no case, except the simple case of squares, in which the solution is in any sense complete. About the squares there is no mystery; every number is the sum of four squares, and there are infinitely many numbers which cannot be expressed by fewer.

3. I will next raise the question *whether the number* $2^{137}-1$ *is prime*. I said that I would include one question which does not interest me particularly; and I should like to explain to you the kind of reasons which damp down my interest in this one. I do not know the answer, and I do not care greatly what it is.

The problem belongs to the theory of the so-called "perfect" numbers, which has exercised mathematicians since the times of the Greeks. A number is perfect if, like 6 or 28, it is the sum of all its divisors, unity included. Euclid proved that the number

$$2^m(2^{m+1}-1)$$

is perfect if the second factor is prime; and Euler, 2000 years later, that all *even* perfect numbers are of Euclid's form. It is still unknown whether a perfect number can be odd.

It would obviously be most interesting to know generally in what circumstances a number 2^n-1 is prime. It is plain that this can be so only if n itself is prime, as otherwise the number has obvious factors; and the 137 of my question happens to be the least value of n for which the answer is still in doubt. You may perhaps be surprised that a question apparently so fascinating should fail to arouse me more.

It was asserted by Mersenne in 1644 that the only values of n, up to 257, for which 2^n-1 is prime are

$$2, 3, 5, 7, 13, 17, 19, 31, 67, 127, 257;$$

and an enormous amount of labour has been expended on attempts to verify this assertion. There are no simple general tests by which the primality of a number chosen at random can be determined, and the amount of computation required in any particular case may be appalling. It has, however, been imagined that Mersenne perhaps knew something which later mathematicians have failed to rediscover. The idea is a little fantastic, but there is no doubt that, so long as the possibility remained, arithmeticians were justified in their determination to ascertain the facts at all costs. "The riddle as to how Mersenne's numbers were discovered remains unsolved," wrote Mr. Rouse Ball in 1891. Mersenne, he observes, was a good mathematician, but not an Euler or a Gauss, and he inclines to attribute the discovery to the exceptional genius of Fermat, the only mathematician of the age whom any one could suspect of being hundreds of years ahead of his time.

These speculations appear extremely fanciful now, for the bubble has at last been pricked. It seems now that Mersenne's assertion, so far from hiding unplumbed depths of mathematical profundity, was a conjecture based on inadequate empirical evidence, and a somewhat unhappy one at that. It is now known that there are at least four numbers about which Mersenne is definitely wrong; he should have included at any rate 61, 89, and 107, and he should have left out 67. The mistake as regards 61 and 67 was discovered so long ago as 1886, but could be explained with some plausibility, so long as it stood alone, as a merely clerical error. But when Mr. R. E. Powers, in 1911 and 1914, proved that Mersenne was also wrong about 89 and 107, this line of defence collapsed, and it ceased to be possible to take Mersenne's assertion seriously.

The facts may be summed up as follows. Mersenne makes fifty-five assertions, for the fifty-five primes from 2 to 257. Of these assertions forty are true, four false, and eleven still doubtful. Not a bad result, you may think; but there is more to be said. Of the forty correct assertions many, half at least, are trivial, either because the numbers in question are comparatively small, or because they possess quite small and easily detected divisors. The test cases are those in which the numbers are prime, or Mersenne asserts that they are so; there are only four of these cases which are difficult and in which the truth is known; and in these Mersenne is wrong in every case but one.

It seems to me, then, that we must regard Mersenne's assertion as exploded; and for my part it interests me no longer. If he is wrong about 89 and 107, I do not care greatly whether he is wrong about 137 as well, and I should regard the computations necessary to decide as very largely wasted. There are so many much more profitable calculations which a computer could undertake.

I hope that you will not infer that I regard the problem of perfect numbers as uninteresting in itself; that would be very far from the truth. There are at least two intensely interesting problems. The first is the old problem, which so many mathematicians have failed to solve, whether a perfect number can be odd. The second is whether the number of perfect numbers is infinite or not. If we assume that all perfect numbers are even, we can state this problem in a still more arresting form. *Are there infinitely many primes of the form* 2^n-1? I find it difficult to imagine a problem more fascinating or more intricate than that. It is plain, though, that this is a question which computation can never decide, and it is very unlikely that it can ever give us any data of serious value. And the problem itself really belongs to a different chapter of the theory, to which I should like next to direct your attention.

4. *Are there infinitely many primes of the form* n^2+1? Let me first remind you of some well-known facts in regard to the distribution of primes.

There are infinitely many primes; their density decreases as the numbers increase, and tends to zero when the numbers tend to infinity. More accurately, the number of primes less than x is, to a first approximation,

$$\frac{x}{\log x}.$$

The chance that a large number n, selected at random, should be prime is, we may say, about $\frac{1}{\log n}$.

Still more precisely, the "logarithm-integral"

$$\mathrm{Li}\, x = \int_2^x \frac{dt}{\log t}$$

gives a very good approximation to the number of primes. This number differs from $\mathrm{Li}\, x$ by a function of x which oscillates continually, as Mr. Littlewood, in defiance of all empirical evidence to the contrary, has shown, between positive and negative values, and is sometimes large, of the order of magnitude $\sqrt{x}$ or thereabouts, but always small in comparison with the logarithm-integral itself.

Except for one lacuna, which I must pass over in silence now, this problem of the general distribution of primes, the first and central problem of the theory, is in all essentials solved. But a variety of most interesting problems remain as to the distribution of primes among numbers of special forms. The first and simplest of these is that of the arithmetical progressions: *How are the primes distributed among all possible arithmetical progressions $an+b$?* We may leave out of account the case in which a and b have a common factor; this case is trivial, since $an+b$ is then obviously not prime.

The first step towards a solution was made by Dirichlet, who proved for the first time, in 1837, that any such arithmetical progression contains an infinity of primes. It has since been shown that the primes are, to a first approximation at any rate, distributed evenly among all the arithmetical progressions. When we pursue the analysis further, differences appear; there are on the average, for example, more primes $4n+3$ than primes $4n+1$, though it is not true, as the evidence of statistics has led some mathematicians to conclude too hastily, that there is always an excess to whatever point the enumeration is carried.

The problem of the arithmetical progressions, then, may also be regarded as solved, and the same is true of the problem of the primes of a given quadratic form, say $am^2+2bmn+cn^2$, homogeneous in the two variables m and n. To take, for example, the simplest and most striking case, there is the natural and obvious number of primes m^2+n^2. A prime is of this form, as I have mentioned already, if, and only if, it is of the form $4k+1$. The quadratic problem reduces here to a particular case of the problem of the arithmetical progressions.

When we pass to cubic forms, or forms of higher degree, we come to the region of the unknown. This, however, is not the field of inquiry which I wish now to commend to your attention. The quadratic forms of which I have spoken are forms in two independent variables m and n; the form n^2+1 of my question is a non-homogeneous form in a single variable n, the simplest case of the general form $an^2+2bn+c$. It is clear that one may ask the same question for forms of any degree: are there, for example, infinitely many primes n^3+2 or n^4+1? I do not choose n^3+1, naturally, because of the obvious factor $n+1$.

This problem is one in which computation can still play an important part. You will remember that I stated the same problem for perfect numbers. There a computer is helpless. For the numbers 2^n-1, which dominate the theory, increase with unmanageable rapidity, and the data collected by the computers appear, so far as one can judge, to be almost devoid of value. Here the data are ample, and, though the question is still unanswered, there is really strong statistical evidence for supposing a particular answer to be true. It seems that the answer is affirmative, and that there is a definite approximate formula for the number of primes in question. This formula is

$$\tfrac{1}{2}\mathrm{Li}\,\sqrt{x}\times\left(1+\tfrac{1}{3}\right)\left(1-\tfrac{1}{5}\right)\left(1+\tfrac{1}{7}\right)\left(1+\tfrac{1}{11}\right)\ldots,$$

where the product extends over all primes p, and the positive sign is chosen when p is of the form $4n+3$. Dr. A. E. Western has submitted this formula to a most exhaustive numerical check. It so happens that Colonel Cunningham some years ago computed a table of primes n^2+1 up to the value 15,000 of n, a limit altogether beyond the range of the standard factor tables, and Cunningham's table has made practicable an unusually comprehensive test. The actual number of primes is 1199, while the number predicted is 1219. The error, less than 1 in 50, is much less than one could reasonably expect. The formula stands its test triumphantly, but I should be deluding you if I pretended to see any immediate prospect of an accurate proof.

5. The last problem I shall state to you is this: *Are there infinitely many prime-pairs p, $p+2$?* One may put the problem more generally: *Does any group of primes, with assigned and possible differences, recur indefinitely, and what is the law of its recurrence?*

I must first explain what I mean by a "possible" group of primes. It is possible that p and $p+2$ should both be prime, like 3, 5, or 101, 103. It is not possible (unless p is 3) that p, $p+2$ and $p+4$ should *all* be prime, for one of them must be a multiple of 3; but p, $p+2$, $p+6$ or p, $p+4$, $p+6$ are possible triplets of primes. Similarly

$$p,\ p+2,\ p+6,\ p+8,\ p+12$$

can all be prime, so far as any elementary test of divisibility shows, and in fact 5, 7, 11, 13 and 17 satisfy the conditions. It is easy to define precisely what we understand by a "possible" group. We mean a group the differences in which, like 0, 2, 6, have at least one missing residue to every possible modulus. The "impossible" group 0, 2, 4 does not satisfy the condition, for the remainders after division by 3 are 0, 2, 1, a complete set of residues to modulus 3. There is no difficulty in specifying possible groups of any length we please.

We define in this manner, then, a "possible" group of primes, and we put the questions: Do all possible groups of primes actually occur, do they recur indefinitely often, and how often on the average do they recur? Here again it would seem that the answers are affirmative, that all possible groups occur, and continue to occur for ever, and with a frequency the law of which can be assigned. The order of magnitude of the number of prime-pairs, p, $p+2$, or p, $p+4$, or p, $p+6$, both members of which are less than a large number x, is, it appears,

$$\frac{x}{(\log x)^2}.$$

The order of magnitude of the corresponding number of triplets, of any possible type, is

$$\frac{x}{(\log x)^3},$$

and so on generally. Further, we can assign the relative frequencies of pairs or triplets of different types; there are, for example, about twice as many pairs the difference of which is 6 as there are pairs with the difference 2. All these results have been tested by actual enumeration from the factor tables of the first million numbers; and a physicist would probably regard them as proved, though we of course know very well that they are not.

There is a great deal of mathematics the purport of which is quite impossible for any amateur to grasp, and which, however beautiful and important it may be, must always remain the possession of a narrow circle of experts. It is the peculiarity of the theory of numbers that much of it could be published broadcast, and would win new readers for the *Daily Mail.* The positive integers do not lie, like the logical foundations of mathematics, in the scarcely visible distance, nor in the uncomfortably tangled foreground, like the immediate data of the physical world, but at a decent middle distance, where the outlines are clear and yet some element of mystery remains. There is no one so blind that he does not see them, and no one so sharp-sighted that his vision does not fail; they stand there a continual and inevitable challenge to the curiosity of every healthy mind. I have merely directed your attention for a moment to a few of the less immediately conspicuous features of the landscape, in the hope that I may sharpen your curiosity a little, and that some may feel tempted to walk a little nearer and take a closer view.

The Organisation of Research.[1]

By Principal J. C. Irvine, C.B.E., D.Sc., LL.D., F.R.S.

THE British Association was the product of an age rather than the inspiration of any one man, yet of those who first gave practical effect to the movement which has spread scientific learning and has bound its devotees in a goodly fellowship there was no more eager spirit than Sir David Brewster. It is not an exaggerated claim that it was he who founded the British Association. One may trace his enlightened action to a desire to combat the apathy and distrust shown by the Government of his day towards scientific work and even scientific workers. Only in the historical sense can I claim any relationship with Brewster. It is my privilege to occupy the Principalship he once held, and I cannot escape from the thought that the daily tasks now mine were once his.

It is thus inevitable that to-day a name often in my mind should spring once more into recollection, especially as my distinguished predecessor was present at the first Hull meeting in 1853, when he contributed two papers to Section A. Chemists should be among the first to pay grateful tribute to Brewster's efforts on behalf of science, and I propose, therefore, to include in my address a review of the position scientific chemistry has won since his day in public and official estimation. Moreover, at the express suggestion of some of our members whose opinions cannot be disregarded, I am induced to add the consideration of the new responsibilities chemists have incurred now that so many of Brewster's hopes have been realised. These were recently submitted by me to another audience and, through the medium of an article in NATURE (July 22, p. 131), are possibly known to you already, but I agree with my advisers that their importance warrants further elaboration and wider discussion.

It would be idle to recall the lowly position of chemistry as an educative force in this country, or to reconstruct the difficulties with which the scientific chemist was confronted during the first thirty years of the nineteenth century. Present difficulties are serious enough, and press for all our attention, without dwelling unduly on troubles of the past. But we must at least remember that in the early days of the British Association "schools" of chemistry were in their infancy, and that systematic instruction in the science was difficult to obtain. Another point of fundamental importance which has to be borne in mind is that the masters of the subject were then for the most part solitary workers.

It is difficult for us, looking back through the years, to realise what it must have meant to search for truth under conditions which were discouraging, if not actually hostile. Yet, although his labours were often thankless and unrewarded, the chemist of the time was probably a riper philosopher and a finer enthusiast than his successor of to-day. He pursued his inquiries amid fewer distractions, and in many ways his lot must have been happy, save when tormented by the thought that a subject so potent as chemistry in developing the intellectual and material welfare of the community should remain neglected to an extent which to us seems incredible.

Public sympathy was lacking, Government support was negligible or grudgingly bestowed, and there was little or no co-operation between scientific chemistry and industry. As an unaided enthusiast the chemist was left to pursue his way without the stimulus, now happily ours, which comes from the feeling that work is supported by educated and enlightened appreciation.

Let me quote from one of Faraday's letters now in my possession and so far as I can trace, unpublished. Writing to a friend immediately before the foundation of the British Association, he relates that a manufacturer had adopted a process developed in the course of an investigation carried out in the Royal Institution. The letter continues: "He" (the manufacturer) "writes me word that, having repeated our experiments, he finds the product very good, and as our information was given openly to the world he, as a matter of compliment, has presented me with some pairs of razors to give away." If ever there was a compliment

[1] From Part I of the presidential address delivered to Section B (Chemistry) of the British Association at Hull on Sept. 7.

which could be described as empty, surely this was one; yet the letter gives the impression that Faraday himself was quite content with his reward.

It is perhaps unfair to quote Faraday as a type, for few men are blessed with his transparent simplicity of character, but there is obviously a great gulf fixed between the present day and a time when a debt of honour could be cancelled in such a manner. A little reflection will show that the British Association has played a useful part in discrediting the idea that because so much scientific discovery is given "openly to the world," those who profit by such discoveries should be absolved from their reasonable obligations. Even where scientific workers do not expect or desire personal reward, the institutions which provide them with their facilities are often sorely in need. The recognition, not yet complete, but more adequate than once was the case, that the labourer is worthy of his hire, represents only one minor change which the years have brought.

An even greater contrast, embodying more important principles, is found in the changed attitude of the State towards scientific education and discovery. Remember Brewster's fond hope that, by means of our Association, the whole status of science would be raised, and that a greater measure of support and encouragement would be received from the Government. How eagerly the venerable physicist must have listened to the Presidential Address delivered at the twenty-third meeting of the Association assembled in Hull for the first time. It dealt with many problems familiar to him. No doubt he followed with keen interest the account of the observations on nebulæ made with Lord Rosse's telescope, and appreciated the references to the work of Joule and Thomson. The address was a masterly synopsis of scientific progress, but from time to time a new note steals in. There is a significant reference to a consultation with the Chancellor of the Exchequer, another to a conversation with Mr. Gladstone, and a third to a working arrangement concluded with the Admiralty. These would fall sweetly on Brewster's ear, and he would cordially approve of the report of our Parliamentary Committee, which had established sympathetic contact with the House of Commons. He could not fail to be impressed with the changes a few years had brought.

Let us bridge the further gap of sixty-nine years which separates us from that day. The contrast is amazing, and once more we can trace the steady, persistent influence of the British Association in bringing about what is practically a revolution in public and official opinion. We have learned many lessons. The change has come suddenly, but it was not spontaneous. Many years had to be spent in disseminating the idea that research is a vital necessity, and toward this end presidents of our Association have not hesitated, year after year, to add the weight of their influence and eloquence. It was courageous of them to do so. I would refer you particularly to the forcible appeals made by Sir James Dewar at Belfast and Sir Norman Lockyer at Southport, when the plea for more research was laid before the Association, and thus found its way by the most direct channel to the press and to the public. No doubt many other factors have played a part in creating a research atmosphere in this country, but the steady pressure exerted by the British Association is not the least important of these influences.

The principles of science are to-day widely spread; systematic scientific training has found an honourable place in the schools and in the colleges; above all, there is the realisation that much of human progress is based on scientific inquiry, and at last this is fostered and, in part, financed as a definite unit of national educational policy. Public funds are devoted to provide facilities for those who are competent to pursue scientific investigations, and in this way the State, acting through the Department of Scientific and Industrial Research, has assumed the double responsibility of providing for the advancement of knowledge and for the application of scientific methods to industry. Scientific workers have been given the opportunities they desired, and it remains for us to justify all that has been done. We have to-day glanced briefly at the painful toil and long years of preparation; now it falls to us to sow the first crop and reap the first harvest.

Thanks to the wisdom and foresight of others, it has been possible to frame the Government policy in the light of the experience gained with pre-existing research organisations. The pioneer scheme of the kind is that administered by the Commissioners of the 1851 Exhibition, who since 1890 have awarded research scholarships to selected graduates. When in 1901 Mr. Carnegie's benefaction was applied to the Scottish Universities the trustees wisely determined to devote part of the revenues to the provision of research awards which take the form of scholarships, fellowships, and research lectureships. These have proved an immense boon to Scottish graduates, and the success of the venture is sufficiently testified by the fact that the Government research scheme was largely modelled on that of the Carnegie Trust.

In each of these organisations chemistry bulks largely, and the future of our subject is intimately connected with their success or failure. The issue lies largely in our hands. We must not forget that we are only at the beginning of a great movement, and that fresh duties now devolve upon us. It was my privilege for some years to direct the work of a chemistry institute, where research was organised on lines which the operation of the Government scheme will make general. If, from the very nature of things, my experience cannot be lengthy it is at least intimate, and I may perhaps be allowed to lay before you my impressions of the problems we have to face.

Two main objectives lie before us: the expansion of useful learning and the diffusion of research experience among a selected class. This class in itself will form a new unit in the scientific community, and from it will emerge the "exceptional man" to whom, quoting Sir James Dewar, "we owe our reputation and no small part of our prosperity." When these words were uttered in 1902 it was a true saying that "for such men we have to wait upon the will of Heaven." It is still true, but there is no longer the same risk that the exceptional man will fall by the way through lack of means. Many types of the exceptional man will be forthcoming, and you must not imagine that I am regarding him merely as one who will occupy a university chair. He will be found more frequently in industry, where his function will

be to hand on the ideas inspired by his genius to the ordinary investigator.

I have no intention of wearying you by elaborating my views on the training required to produce these different types. My task is greatly simplified if you will agree that the first step must be systematic experience in pure and disinterested research, without any reference to the more complicated problems of applied science. This is necessary, for if our technical research is to progress on sound lines the foundations must be truly laid. I have no doubt as to the prosperity of scientific industries in this country so long as we avoid hasty and premature specialisation in those who control them. We may take it that in the future the great majority of expert chemists will pass through a stage in which they make their first acquaintance with the methods of research under supervision and guidance. The movement is already in progress. The Government grants are awarded generously and widely. The conditions attached are moderate and reasonable, and there is a rush to chemical research in our colleges. Here, then, I issue my first note of warning, and it is to the professors. It is an easy matter to nominate a research student; a research laboratory comfortably filled with workers is an inspiring sight, but there are few more harassing duties than those which involve the direction of young research chemists. No matter how great their enthusiasm and abilities, these pupils have to be trained, guided, inspired, and this help can come only from the man of mature years and experience. I am well aware that scorn has been poured on the idea that research requires training. No doubt the word is an expression of intellectual freedom, but I have seen too many good investigators spoiled and discouraged through lack of this help to hold any other opinion than that training is necessary. I remember, too, years when I wandered more or less aimlessly down the bypaths of pointless inquiries, and I then learned to realise the necessity of economising the time and effort of others.

The duties of such a supervisor cannot be light. He must possess versatility; for although a "research school" will doubtless preserve one particular type of problem as its main feature, there must be a sufficient variety of topics if narrow specialisation is to be avoided. Remember, also, that there can be no formal course of instruction suitable for groups of students, no common course applicable to all pupils and all inquiries. Individual attention is the first necessity, and the educative value of early researches is largely derived from the daily consultations at the laboratory bench or in the library. The responsibility of becoming a research supervisor is great, and, even with the best of good will, many find it difficult to enter sympathetically into the mental position of the beginner. An unexpected result is obtained, an analysis fails to agree, and the supervisor, out of his long experience, can explain the anomaly at once, and generally does so. If the pupil is to derive any real benefit from his difficulties, his adviser must for the moment place himself in the position of one equally puzzled, and must lead his collaborator to sum up the evidence and arrive at the correct conclusion for himself. The policy thus outlined is, I believe, sound, but it makes severe demands on patience, sympathy, and, above all, time.

Research supervision, if conscientiously given, involves the complete absorption of the director's energy and leisure. There is a rich reward in seeing pupils develop as independent thinkers and workers, but the supervisor has to pay the price of seeing his own research output fade away. He will have more conjoint papers, but fewer individual publications, and limitations will be placed on the nature of his work by the restricted technique of his pupils.

I have defined a high standard, almost an ideal, but there is, of course, the easy alternative to use the technical skill of the graduate to carry out the more laborious and mechanical parts of one's own researches, to regard these young workers as so many extra pairs of hands. I need not elaborate the outcome of such a policy.

There is another temptation, and that, in an institution of university rank, is for the professor to leave research training in the hands of his lecturers, selecting as his collaborators only those workers who have passed the apprenticeship stage. This, I am convinced, is a mistake. Nothing consolidates a research school more firmly than the feeling that all who labour in its interests are recognised by having assigned to them collaborators of real ability.

I am not yet done with the professor and his staff, for they will have other matters to attend to if research schools are to justify their existence and to do more than add to the bulk of our journals In many cases it will be found that the most gifted of the young workers under their care lack what, for want of a better expression, is known as "general culture." Remember, these graduates have just emerged from a period of intensive study in which chemistry and the allied sciences have absorbed most of their attention. For their own sake and in the interests of our subject, they must be protected from the criticism that a scientific education is limited in outlook and leads to a narrow specialism. The research years are plastic years, and many opportunities may be found in the course of the daily consultations "to impress upon the student that there is literature other than the records of scientific papers, and music beyond the range of student songs." I mention only two of the many things which may be added to elevate and refine the research student's life. Others will at once occur to you, but I turn to an entirely different feature of research training, for which I make a special plea: I refer to the inculcation of business-like methods. You will not accuse me, I hope, of departing from the spirit of scholarship or of descending into petty detail, but my experience has been that research students require firm handling. Emancipated as they are from the restrictions of undergraduate study, the idea seems to prevail that these workers ought to be excused the rules which usually govern a teaching laboratory, and may therefore work in any manner they choose. It requires, in fact, the force of a personal example to demonstrate to them that research work can be carried out with all the neatness and care demanded by quantitative analysis. Again, in the exercise of their new freedom young collaborators are inclined to neglect recording their results in a manner which secures a permanent record and is of use to the senior collaborator. As a rule, the compilation of results for publication is not

done by the experimenter, and a somewhat elaborate system of records has to be devised. It should be possible, twenty years after the work has been done, to quote the reasons which led to the initiation of each experiment, and to trace the source and history of each specimen analysed, or upon which standard physical constants have been determined. I need not enter into detail in this connexion beyond stating that, although a system which secures these objects has for many years been adopted in St Andrews, constant effort is required to maintain the standard.

One of the greatest anxieties of the research supervisor is, however, the avoidance of extravagance and waste. The student is sometimes inclined to assume a lordly attitude and to regard such matters as the systematic recovery of solvents beneath his notice. My view is that, as a matter of discipline as much as in the interests of economy, extravagant working should not be tolerated. There is naturally an economic limit where the time spent in such economies exceeds in value the materials saved, and a correct balance must be adjusted. It is often instructive to lay before a research worker an estimate of the cost of an investigation in which these factors of time and material are taken into account. As a general rule it will be found that the saving of material is of greater moment than the loss of time. The point may not be vitally important in the academic laboratory, but in the factory, to which most of these workers eventually migrate, they will soon have the lesson thrust upon them that their time and salary bear a small proportion to costs of production.

You will see I have changed my warning from the professor to the student. A student generation is short. In a few years, when almost as a matter of course the best of young chemists will qualify for the Doctor of Philosophy degree, it will be forgotten that these facilities have come to us, not as a right, but as a privilege. Those who reap the advantages of these privileges must prove that the efforts made on their behalf have been worth while.

Looking at the position broadly, if one may criticise the research schemes of to-day, it is in the sense that the main bulk of support is afforded to the research apprentice, and the situation has become infinitely harder for the supervisor in that new and onerous tasks are imposed upon him. To expect him to undertake his normal duties and, as a voluntary act, the additional burden of research training is to force him into the devastation of late hours and overwork. The question is at once raised—Are we using our mature research material to the best advantage, and is our policy sufficiently focussed on the requirements of the experienced investigator? I think it will generally be agreed that members of the professor or lecturer class who join in the movement must be relieved in great measure of teaching and administrative work. I am decidedly of the opinion that the research supervisor must be a teacher, and must mingle freely with undergraduates, so as to recognise at the earliest possible stage the potential investigators of the future and guide their studies. To meet this necessity universities and colleges must realise that their curriculum has been extended and that staffs must be enlarged accordingly. There could then be definite periods of freedom from official duties for those who undertake research training as an added task. Opportunities must also be given to these "exceptional men" to travel occasionally to other centres and refresh themselves in the company of kindred workers. It is evident that our universities are called upon to share the financial burden involved in a national research scheme to a much greater extent than possibly they know.

I may perhaps summarise some of the conclusions reached in thinking over these questions. The first and most important is that in each institution there should be a Board or Standing Committee entrusted with the supervision of research. The functions of such a body would be widely varied and would include:—

1. The allocation of money voted specifically from university or college funds for research expenses.

2. The power to recommend additions to the teaching staff in departments actively engaged in research.

3. The recommendation of promotions on the basis of research achievement.

4. The supervision of regulations governing higher degrees.

Among the more specific problems which confront this Board are the following:—

1. The creation of research libraries where reference works can be consulted immediately.

2. The provision of publication grants, so that where no periodical literature is available the work will not remain buried or obscure.

3. The allocation of travelling grants to enable workers to visit libraries, to inspect manufacturing processes, and to attend the meetings of scientific societies.

There is one thing which a Research Board should avoid. It is, I am convinced, a mistake for a governing body to call for an annual list of publications from research laboratories. Nothing could be more injurious to the true atmosphere of research than the feeling of pressure that papers must be published or the Department will be discredited.

What I have said so far may seem largely a recital of new difficulties, but they are not insurmountable, and to overcome them adds a zest to life. It would have taken too long to go more fully into details, and I have tried to avoid making my address a research syllabus, merely giving in general terms the impressions gained during the twenty years in which the St. Andrews Research Laboratories have been in existence.

I have confined myself to the first stage in the research development of the chemist. His future path may lead him either to the factory or to the lecture-room, and in the end the exceptional man will be found in the director's laboratory or in the professor's chair. However difficult these roads may prove, I feel that with the financial aid now available, supported by the self-sacrificing labours of those who devote themselves to furthering this work, he has the opportunity to reach the goal. It is the beginning of a new scientific age, and we may look forward confidently to the time when there will be no lack of trained scientific intellects to lead our policy and direct our efforts in all that concerns the welfare of the country.

The Total Solar Eclipse of September 21.

By Dr. A. C. D. CROMMELIN.

THERE are at present in the Saros Cycle two series of eclipses which have unusual length of totality; one including those of 1865, 1883, 1901, 1919, the other including the great Indian eclipse of 1868, in which the spectroscope was first applied to the prominences; also those of 1886 (West Indies) and 1904 (Pacific). The forthcoming eclipse, September 21, being three Saroses after that of 1868, is in nearly the same longitude, but has moved southward, the only land stations available being the Maldives, Christmas Island, and Australia.

The Maldives have the disadvantages of a rather low sun, some difficulty of access, owing to the reefs surrounding the islands, probability of high wind, together with a poor health record for European visitors; they are, however, being occupied by Mr. Evershed. Christmas Island lies in the longitude of maximum totality (6 minutes), but being near the northern limit of totality it will enjoy only 3¾ minutes. This is, however, amply long enough for the programme planned. The station is occupied by Messrs. Jones and Melotte from Greenwich, their equipment consisting of the 13-inch astrographic equatorial, on a mounting specially constructed for the low latitude of the station. When the same instrument was used in Brazil in 1919 the star-images were diffused, owing probably to slight warping of the cœlostat mirror by the heat of the sun before totality. The unsuitability of the cœlostat had been foreseen, but the short interval between the armistice and the departure of the expedition made it impossible to provide an equatorial mounting.

On the present occasion it is desired to secure a completely satisfactory check on the 1919 results; these tended to confirm the amount of shift of light by the sun's gravitation predicted by Einstein: the difference in the results given by the two instruments in Brazil was, however, too large to permit the results to be taken as absolutely final, and a further test is desirable. The star-field at this totality is, unfortunately, much less favourable than that in 1919, which was probably the field containing the largest number of bright stars close to the ecliptic. There are, however, a fair number of stars of the eighth magnitude or brighter in the present field, and it is hoped that these may be photographed with somewhat longer exposures than those given before. The corona will probably be of the "Minimum" type, with little extension near the poles; this should enable stars fairly near the sun, which will have a large factor of shift, to be photographed.

Christmas Island is occupied by a Phosphate Company, under Scottish management, which has given great assistance to the expedition in transporting their baggage, in erecting huts, providing workmen, etc. Reports received in July stated that the adjustment of the instruments was complete, but that the weather during May had been very wet, and little observing was possible; check plates of the eclipse field had, however, been secured. The rainy season was, however, nearly at an end, and it was hoped that more work would shortly be possible; in addition to the eclipse programme it was planned to take a series of photometric plates, to connect the magnitude scales of the northern and southern hemispheres. Profs. Freundlich and Einstein also arranged to observe from Christmas Island, their programme being much the same as that of the British observers.

The station on the coast of West Australia has a high sun, long totality, and excellent weather prospects; but it is difficult of access, it being necessary to anchor some miles out, and land in small boats through surf. Several parties are there; that with the largest equipment is from the Lick Observatory, under Prof. Campbell. This party also makes the Einstein problem the chief item of the programme. To avoid a long stay at the eclipse camp the check plates were taken at Fiji on the voyage out. Other parties at this station are from Canada and from Perth (Australia).

The observatories of Adelaide, Melbourne, and Sydney are sending expeditions to stations in Central Australia and in Queensland. The weather prospects are good at both, but the sun in Queensland is rather low. They are understood to be attempting the Einstein problem, in addition to the older eclipse work of photography of the corona and its spectrum.

There is every reason to hope for success at some of the stations; fine weather at all of them should lead to results of a decisive character on the Einstein problem. The results will not be available for some time, as the plates will not be measured till the return of the different parties. They will, however, be developed, *in situ*, which will permit a good idea of their character to be formed. In this connexion it may be noted that there is no cable to Christmas Island, but it is expected that a Dutch man-of-war will be there, which might send a wireless message to Java.

The Deflection of Light in a Gravitational Field.

By HERBERT DINGLE.

FROM an experimental point of view, Einstein's general theory of relativity is at present in an ambiguous position. It is well known that there are three conceivable tests between its conclusions and those of the traditional ideas which it attempts to displace. With regard to the first of these—the movement of the perihelion position of Mercury—the success of the theory is decidedly impressive; all the more so, perhaps, because the result was stumbled upon, as it were, involuntarily. In seeking first the gravitational field of the sun, Einstein found the true orbit of Mercury added unto him. On the other hand, the predicted displacement of the solar spectrum lines certainly conjures up a serious obstacle. The evidence,

it is true, is contradictory, but, such as it is, it seems to show a balance against the existence of the displacement. The extreme difficulty and complexity of the experimental work must, nevertheless, be borne in mind. Perhaps it is scarcely possible, in the present state of our knowledge and experimental equipment, to obtain a definite solution of the problem. The third test—concerning the deflection of light in a gravitational field—accordingly becomes of very considerable importance, and to many minds constitutes the deciding factor in their judgment of the theory.

Consequently, the chief item in the programme of the Royal Astronomical Society's expedition to Christmas Island, on the occasion of the total solar eclipse of September 21, will be the investigation of this particular problem. It will be remembered that the original test, on May 29, 1919, was considered by the observers and a large number of others to give conclusive evidence in favour of the relativity theory: it was this result, in fact, that directed general attention to the theory, and made Einstein, for a brief spell, a noteworthy figure in public esteem. The interpretation of the observations, however, has been subjected to various criticisms. A refracting atmosphere of the sun has been proposed. Attempts have been made to explain the effect as a result of terrestrial atmospheric refraction arising from a temperature gradient across the boundary of the moon's shadow-cone. Still more serious is the evidence of the mutual displacement of adjacent photographic images: the question arises whether the observed positions of the star images might not be, to some extent, dependent on the intensity of the coronal light. It must be admitted that the criticisms have been well met. Nevertheless, so fundamentally important a matter can scarcely be regarded as finally settled by a single set of observations, and the repetition which is about to take place is anything but a superfluous confirmation of previous knowledge.

It will be opportune at this time to recall the nature of the problem, and see wherein lies the difference between the traditional and the relativity conceptions which makes the prospective test possible. From the time of Newton until quite recently, gravitation has been looked upon as an essential property of matter—as characteristic as the property of inertia. Whenever we find matter showing the unmistakable effects of inertia, we find also evidence of gravitational influence. The universality of these twin phenomena has so impressed physicists that they have come to look upon them as the fundamental properties of matter. Matter is, by definition, that which has inertia and exerts gravitational attraction. Nevertheless, it is well to point out that inertia and gravitation are not the properties by which matter is generally recognised. With regard to most of the matter in the universe, there is no evidence that they exist. We announce the presence of matter when we *see* it: in other words, matter everywhere has the power of emitting or absorbing light—or, more generally, radiation. We see light, and we deduce a star; the light fluctuates, and we deduce absorbing matter. If, according to the true scientific method, we establish our fundamental conceptions on the groundwork of pure observation, we must place the power to radiate and absorb light at least as deep down in the nature of matter as the inertial-gravitational property. The recognition of either property is universally accepted as evidence of the existence of matter.

The difference with which we are concerned between the traditional and the relativistic conceptions may be expressed in this way: that whereas the older view gives no *a priori* indication of a relation between the two fundamental material influences, gravitation and light, it is an essential condition of the relativity theory that such a relation exists. A large and valuable system of thought has been built up—mainly during the last hundred years—in which radiation and gravitation are completely independent. Radiation submits to analysis and invites correlation with other physical phenomena; gravitation stands inaccessibly apart. The complex organism of electromagnetism, embracing as it does radiation, the æther, electricity, magnetism, the atom—even inertia (for radiation possesses inertia) —seems capable of assimilating the whole of physics—except gravitation. Matter appears to be the source of two streams of phenomena, one summarised in electromagnetism and the other in gravitation, and between them there is a great gulf fixed. The completeness of the duality lies, of course, only in the conceptions. Experimental evidence of a bridge across the gulf might have arisen at any time. Standing now on the bridge, it seems a little strange that it was not sought before. Inertia, in submitting to the electromagnetic scheme, might carry with it the gravitational property with which, in material bodies, it is always associated, and the electromagnetic inertia of light might be accompanied by a proportionate power to exert and respond to gravitational influence. There is no reason, according to pre-relativity physics, why it should, but neither is there any reason why it should not. The impotence of the electromagnetic theory even to suggest the more probable of the alternatives is its main defect.

There is no such ambiguity in the utterances of the relativity theory. Here gravitation—as a physical existence giving rise to a gravitational field—is ignored: the field alone is considered. The seat of the phenomenon is not sought in the secret nature of matter; it is sought in the space surrounding matter, and is, in fact, regarded as a property of that space—or, rather, space-time. The justification for this view is found in the facts, first, that the evidence for the existence of gravitation is the observed acceleration of one body in the neighbourhood of another; and, second, that the acceleration produced by one body in another is independent of every property of the latter except its position relative to the former. Now a phenomenon manifesting itself as an acceleration (involving the dimensions of space and time only) and producing effects depending only on position, can be submitted to a geometrical treatment, provided that the dimension of time is added to those of space. Instead of speaking of the curved paths of bodies in a homogeneous space-time, we can speak of the straight paths of bodies in a heterogeneous space-time. The same phenomenon is indicated by both statements. Expressed in this way, it seems as though there could be no difference between the two views, except that one might be more convenient than the other. Considered from a physical

point of view, however, the difference between them is fundamental, and issues into the three experimental tests referred to. The deflection of light in a gravitational field follows naturally, if gravitation is attributed to the heterogeneity of space-time. Any entity—whether light or matter—pursuing its natural path, will appear to change the character of its motion when the space-time through which it travels departs from the simple Euclidean type. It does not matter what the moving thing is; all that counts is the region through which it moves. The dilemma of the older theory does not exist from the relativistic point of view: light must be deflected or the theory must be abandoned.

Fortunately, the amount of the deflection which relativity demands is measurably different from that which the electromagnetic theory allows. According to the relativity theory, a ray of light which just clears the sun's limb should suffer a deviation of about $1''\cdot75$; according to the other view, the deviation should be either half of this or nothing at all. It is this difference that makes possible the test which is about to be applied. On September 21 the sun will be leaving the constellation Virgo—very close to the celestial equator. The position is not so favourable with respect to neighbouring bright stars as was that of May 29, 1919, when the original test was made. On the other hand, the experience and criticisms arising from the previous attempt are available for the guidance of the present observers, and, granted favourable conditions, there seems to be no reason why the result should not become decisive.

The British Association at Hull.

YORKSHIRE hospitality is proverbial, and it has been very pleasantly manifested during the meeting of the British Association just concluded at Hull. The citizens have in many ways shown themselves to be proud to entertain the Association, and the facilities they have offered to the members have been exceptionally helpful. Each member was provided with a badge, and this was not only a free pass on the quick and convenient tramway system of the city, but also secured personal guidance and interest from citizens in the streets or in vehicles of any kind. It would be impossible for a city to show greater interest in its visitors or to do more to make their sojourn pleasant, and the many attentions have been much appreciated, particularly by officers and other active members of sections who usually have not the time to search for all the amenities which a place of meeting may afford. A number of free luncheons have been provided, and when the days' meetings have been over tea has been served in the writing-room at the Guildhall, and has been found both grateful and comforting to the members. For these and other unusual attentions the Association is no doubt chiefly indebted to the local secretary, Mr. T. Sheppard, curator of the Hull Museums, but with him is associated the town clerk, Mr. H. A. Learoyd, and the generous hospitality would not have been possible without the active interest and support afforded by the Corporation and people of the city. The Handbook to Hull and the East Riding of Yorkshire, edited by Mr. Sheppard and presented to each member, is a volume of permanent value, and as it will be on sale for the low price of five shillings we propose to publish a separate notice of it in an early issue.

At the meeting of the general committee at which the report of the council was presented, a resolution was passed conveying to Prof. Turner the most cordial thanks of the Association for the valuable services he has rendered to science in general and the Association in particular during his nine years' work as one of the general secretaries. In its report the council stated that it had received with great regret Prof. Turner's intimation that he would not be able to attend a meeting in Canada in 1924. Prof. Turner himself pointed out that it was desirable, on various grounds, that his successor should have experience of the working of an annual meeting at home before taking part in one overseas, and he therefore placed his office at the disposal of the general committee as from the Hull meeting. The council and the Association owe a deep debt of gratitude to Prof. Turner for his unremitting care for the interests of the Association as general secretary since 1913, and therefore during a time of exceptional difficulty, including as it has the Australian meeting, the war, the revival of the annual meetings since the war, and the period when, on the death of the late general treasurer and assistant treasurer in 1920, he acted for some months as treasurer in addition to his other work.

Mr. F. E. Smith, director of scientific research at the Admiralty, and secretary of the Physical Society, accepted the invitation of the council to be nominated as Prof. Turner's successor, and the general committee unanimously voted his appointment to the office of general secretary of the Association. The three new members of the council appointed by the general committee are Mr. E. N. Fallaize, Dr. C. S. Myers, and Prof. A. Smithells.

Next year's meeting will be at Liverpool with Sir Ernest Rutherford as president, and in the following year the place of meeting will be Toronto. The invitation to Canada was conveyed by Prof. J. C. Fields and Prof. J. C. McLennan, and it was announced that a grant of about 11,000*l.* would be available towards meeting the travelling and other expenses of visiting members.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS.

EQUAL PAY TO MEN AND WOMEN FOR EQUAL WORK.

IN Prof. F. Y. Edgeworth's address to Section F (Economics) the question whether the wages of men and women should be determined on the same principles—in particular, through universal unrestricted competition—was discussed on purely economic grounds. Notwithstanding the general presumption in favour of *laisser faire*, it is maintained that some regulation is required for desperate competition tending to the

degradation of labour. Such kinds of competition being ruled out, there is advocated an equal labour-market, the same blend of competition and combination, for both sexes alike The unequal pressure of male unions, crowding women into comparatively few occupations, is deprecated, and it is pointed out that a sufficient safeguard against such pressure is not afforded by the interest of the employer seeking to maximise his profits. This insufficiency is explained by a principle widely applicable in economics which may be stated thus. When a quantity is in the neighbourhood of a maximum value, a small change in the conditions on which it depends the independent variables - is generally attended with a *very* small change in the dependent quantity Some suggestions were offered with respect to the difficulty that the value of work is not always measurable without regard to the sex of the worker, *e g* the employment of a woman is less profitable, so far as, other things being equal, a man is generally more useful in an emergency. Lastly, Prof. Edgeworth considered the serious impediment to equality in the labour market caused by the burden of supporting a family which is commonly undertaken by men. The proposal to obviate this difficulty by the endowment of motherhood was examined; objection is taken to the (commonly implied) socialistic transference of enormous sums from one class to another. The objection is not equally directed against subsidies in kind for the purpose of education; nor against the proposal that within the same social grade, or association, the childless should contribute to the support of children.

DR. RIVERS AND THE DEVELOPMENT OF PSYCHOLOGY.

IN Section J (Psychology) the presidential address by Dr C. S Myers was "On the Influence of the late W. H R. Rivers (President-elect of the Section) on the Development of Psychology in Great Britain" Rivers was invited in 1893 (in his thirtieth year) by Michael Foster to Cambridge, where he systematised the first course of practical work in experimental psychology in this country. His earliest experiments there were on colour vision and visual space perception, and he contributed to Schafer's "Textbook of Physiology" an exhaustive article on vision, which is still regarded as the most accurate and careful account of the subject in the English language. He soon extended his observations on colour vision and space perception to the Torres Straits Islanders, the Egyptians and the Todas, his membership of Dr. Haddon's Cambridge Anthropological Expedition to the Torres Straits giving him his first introduction to ethnology. These several investigations will ever stand as models of psychological method. In 1903, on his return from the Todas, he began his memorable share in the striking observations on the recovering cutaneous sensibility of Dr. Head's arm. The distinction therein reached between epicritic and protopathic sensibility laid the foundations of Rivers's later views on instinct, intelligence, dreams, and the unconscious. While working with Head, he was also engaged in studying the effects of alcohol, caffeine, and other drugs on muscular and mental work. These elaborate investigations he published as the Croonian Lectures to the Royal College of Physicians in 1908. By them he advanced the pharmacological study of the effects of drugs on man, showing how important it is to disguise the drug and to provide a control mixture indistinguishable in taste from the disguised drug mixture, so as to avoid the complicating effects of suggestion, interest, and sensory stimulation. From 1907 to 1915 he confined himself to ethnological work, but during the Great War his treatment of the psychoneuroses in the Army and in the Air Force led him back to psychology. A period ensued in which Rivers's psychological genius was released from its former shackles and his intuition was no longer controlled by intellectual doubt. It is difficult to exaggerate the fruitful, stimulating character of his criticisms of Freud and of his views on the unconscious, on instincts, and on dreams which poured forth with such astonishing profusion during the last years of his life. His main object was to give a biological interpretation to the data of psychology. His wide interests, sympathies, attainments, and knowledge, his generosity and honesty, and his devotion to scientific methods inspire us in our common aim—the Advancement of Science.

ORGANISATION OF THE AGRICULTURAL INDUSTRY.

LORD BLEDISLOE, in his address on "The Proper Position of the Landowner in Relation to the Agricultural Industry," delivered before Section M, pointed out that organisation in the interests of the agricultural producer is the chief desideratum of British rural industry, and for this, enlightened leadership is essential. The leader and chief organiser should be the landowner, if he would but take his proper position after due training. Under present conditions it is evident that the unification of the rôles of the landowner and farm tenant is a condition precedent to the full, confident, and enterprising development of the agricultural industry on economic lines Nevertheless, it must be recognised that the system of occupying ownership cannot exist in this country to the entire exclusion of that of landlord and tenant. English law and custom in relation to the settlement of estates and to the letting of farms are now frequently obstructive in nature under the changed conditions, and it might be well if modifications could be brought about *e.g.*, if it were made possible in certain cases to sell part of a settled estate in order to provide the necessary capital for the cultivation or industrial equipment of the remainder of it.

In all continental countries the political power enjoyed by agriculture is founded on the fact that it is an organised industry, whereas in Great Britain it is not. As a result, the continental landowner derives as a rule a net income of 3*l*.-4*l*. per acre, as compared with 1*l*. per acre in the United Kingdom. Much of this may also be attributed to the failure of the British farmer, in the absence of the landowner's stimulus, to utilise the results of education and research, whereas abroad, especially in Germany, more scientific methods are readily adopted, notably in the economic employment of feeding stuffs and fertilisers.

Many suggestions may be made as to methods whereby British agriculture, under the direction not

of the State but of the landowners, may be stabilised on a remunerative basis, among which may be mentioned the organisation of credit facilities, co-operative purchase and sale, utilisation of machinery and power, improvement of livestock sires, establishment of central dairies and bacon factories, the fuller exploitation of all farm products, especially in times of glut, and above all the elimination of superfluous and unnecessary middlemen. Apart from the heavy burden of local and Imperial taxation the toll levied by the middlemen is the main cause of the poverty-stricken condition of the English agricultural labourer; the disparity of the prices paid to the farmer and by the consumer for the same produce was well illustrated by tables.

During the last eight years occupying owners have increased by 49 per cent. and the acreage that they own by 100 per cent.; the political and industrial power resulting from this considerable reinforcement of their class should prove the greatest stimulus to enterprise on the part of landowners. The existence of the Central Landowners' Association is a welcome augury of future corporate efficiency, as its objects are to a great extent economic and constructive. In conclusion Lord Bledisloe emphasised once more the need for the effective organisation of agriculture and for the solidarity of all three classes of the agricultural community, without which continuous progress is difficult of attainment.

Current Topics and Events.

THE Rowett Institute of Research in Animal Nutrition, Aberdeen, was formally opened by H M the Queen on Tuesday, September 12. It will be remembered that the Institute, which in the two years of its existence has done valuable work on problems of animal feeding, is under the control of the University of Aberdeen and the North of Scotland Agricultural College, the director is Dr J. B. Orr. The Institute owes much to the generosity of Dr. J Quiller Rowett, after whom it was named, who contributed a sum of 10,000*l.* towards its endowment (NATURE, September 9, 1920, p. 67). This was followed by another gift for the purpose of purchasing a farm which would allow of expansion of the Institute; H M. Treasury, on the recommendation of the Development Commission, promised a further sum of 20,000*l.* It is the establishment of such institutions as the National Institute of Agricultural Botany and the Rowett Institute of Research in Animal Nutrition which will go far towards improving the unsatisfactory state of our knowledge of food problems, both animal and human.

To the August number of the *Nineteenth Century* Sir Arthur Keith contributes a timely article on the present position of Darwinism as applied to the problem of man's origin The strange action of a strong party among the legislators of Kentucky in America, and ill-informed articles in certain American newspapers, have met with some feeble response in this country; and an authoritative statement of the case which can be understood by the general reader is especially needed at the present time. Sir Arthur Keith has stated the case admirably, and he emphasises the fact that if a new edition of Darwin's "Descent of Man" were prepared to-day, the work would merely need large additions, and scarcely any important revision. The discoveries of the fossil remains of man made since 1871 agree in pointing towards a common ancestry with the apes. The progress in our knowledge of human embryology within the same period has revealed a succession of facts which can be explained only on the theory of descent from lower forms of life. The latest discovery, that the development and growth of all parts of the body are regulated and co-ordinated by a "hormone" mechanism (the pouring of substances into the circulating blood by the ductless glands), leads even to the hope that before long we may begin to learn something about the processes of evolution To the investigator, indeed, Darwinism is not a mere theory, but an instrument of advance, trusted as implicitly as are the Admiralty charts by a navigator.

WE learn from the *Times* that an expedition headed by Capt F Hurley has left Sydney for Port Moresby with the object of exploring New Guinea from the air The party will include an ethnologist and a naturalist. Two seaplanes are being taken and will be used in a four months' air survey of the western portions of British New Guinea. Meanwhile the scientific section of the expedition will navigate the Fly River in a ketch. The cost of the seaplanes is being borne by Mr. L. Hodson, of Sydney. Owing to the densely forested nature and steep slopes of the interior, exploration of New Guinea on foot is most arduous. Capt Hurley's scheme promises some hope of success, but landing places, except along the coast, will be difficult to find The leader's previous experience in exploration was obtained with the Australian Antarctic Expedition. He has also flown across the Australian continent

THE earthquake reported on the morning of August 27 in the Midland Counties was possibly, as Sir George Fordham has suggested in the *Times*, caused by the bursting of a meteorite A tremor and sound were observed at 9 12 A M. (G M T) over an area of about 650 square miles with its centre a few miles south of Birmingham; at Woodhouse Eaves, seven miles north-north-west of Leicester, at 9.13; and at Whissenthorpe, near Oakham, at 9 10. The observed times are so close that it seems probable that all three shocks were due to the same cause, and the detachment of the three areas and their nearly linear arrangement are certainly suggestive of successive explosions of a meteorite.

THE centenary of the Yorkshire Philosophical Society, which was founded in 1822, will be celebrated on Wednesday, September 20 The members of the Society and its guests will be received in the

gardens of the Yorkshire Museum by the president, Mr. W. H. St. Quintin, and a number of congratulatory addresses from national as well as local learned bodies will be read by their representatives. Later, the gathering will go in procession to the Minster, where a short service will be held and an address delivered by the Bishop of Beverley.

THE following have been appointed to the Board of Trustees of the National Portrait Gallery: the Earl of Ilchester, Sir Martin Conway, and Mr. W. B. Hardy, in place of the late Viscount Bryce, Sir Edward Conway, and Viscount Harcourt, respectively.

THE sixty-seventh international annual exhibition of the Royal Photographic Society of Great Britain will be opened on Saturday, September 16, by Mr. S. J. Solomon, president of the Royal Society of British Artists, at 35 Russell Square, W.C.1.

THE Harveian Oration of the Royal College of Physicians of London will be delivered at the college at 4 o'clock on Wednesday, October 18, by Dr. Arnold Chaplin. Sir Maurice Craig is to deliver the Bradshaw Lecture (on "Mental Symptoms in Physical Disease") on November 2. The FitzPatrick Lecture will be given by Dr. R. O. Moon on November 7 and 9. The subject will be "Philosophy and the Post-Hippocratic School of Medicine."

IT has been decided that an Institute of Paint and Varnish Technologists shall be founded, and a dinner is to be held shortly to inaugurate the new Institute. The objects of the Institute will be the dissemination of practical and scientific knowledge by reading and discussing papers, the improvement of technical education, the promotion of research, and the establishment of close relations with the Government and with societies interested in the products of the industry and their application. Applications to attend the inaugural dinner should be forwarded to H. D. Bradford, 42 Ribblesdale Road, S.W.16.

AT a conference of the leading societies in North America that deal with biological subjects, recently held in Washington, it was decided to recommend to the constituent bodies the formation of a Federation of American Biological Societies. The members of the federation are to be societies, not individuals, and the governing body is to be a council consisting of two representatives from each society; the council is to choose an executive committee from its own members. One of the first questions to come before the council, if and when constituted, will be the improvement of biological publications, and a committee is already studying the question in co-operation with a committee from the Division of Biology and Agriculture of the National Research Council of the United States

IN our issue of April 15, p. 486, reference was made to the preparations in progress for the celebration in France of the centenary of the birth of Pasteur. A committee was formed in this country, under the chairmanship of Sir Charles Sherrington, in support of the commemoration measures, among which were the promotion of an exhibition of hygiene and bacteriology in Strasbourg and the erection of a statue of Pasteur before the University. Various amounts have been sent to France from time to time by the British committee, in addition to which it is now stated that a sum of nearly 850*l.* is to be forwarded to the general treasurer of the fund, M. T. Héring. The British committee has expressed the wish that should the amount be greater than that the French committee desire to spend on the statue of Pasteur, the excess should be devoted to some other form of permanent memorial in the University of Strasbourg.

THE programme has been issued of the meetings of the Institute of Metals to be held during the session 1922–23 under the presidency of Mr. Leonard Sumner. The annual May lecture will be delivered on May 2 by Dr. W. Rosenhain. The Scottish Local Section, which has arranged for six meetings in Glasgow, will be under the chairmanship of Mr. James Steven; membership is open to all local members of the Institute, and applications should be addressed to the hon. secretary, Mr. H. H. A. Greer, 50 Wellington Street, Glasgow. The chairman of the Sheffield Local Section is Prof. C. H. Desch, and the hon. secretary, H. P. Gadsby, 193 Sandford Grove Road, Sheffield; an important event in the Sheffield programme is a joint meeting with the Faraday Society for a symposium on stainless and non-corrodible alloys to be held on February 9 at Sheffield.

THE third International Conference of "Psychotechnique appliqué à l'orientation professionnelle" will meet this year at Milan on October 2–5. In order to prevent waste of time it has been decided to limit the discussions to the following subjects:—(*a*) What is meant by vocational aptitudes? (Lahy); (*b*) Natural aptitudes and acquired aptitudes (Décroly, Patrizi); (*c*) The psychological analysis of work (Gemelli, Lipmann); (*d*) Vocational guidance and Taylorism (Bauer); and (*e*) An international unification of tests and individual ratings (Claparède, Mira, Myers). A short paper of about twenty minutes' duration will be given on each subject in order to guide the discussion, and the language used will be French. The general session will be occupied with these subjects, but other meetings to discuss more detailed problems will be held in rooms specially set apart for the purpose. Papers presented at the meeting will be grouped together according to the relationship between them. A room will be reserved for the exhibition of tests, instruments, etc. Those desirous of attending are asked to communicate with the Secretary, III^{me} Conférence Internationale de Psychotechnique, Milan (XIV.), via S. Barnaba 38. October 5 will be spent in visits to scientific and industrial establishments in the neighbourhood of Milan.

DR. M. J. SIRKS takes exception to the notice of his handbook of heredity published in NATURE of July 22, p. 111. He deprecates especially the charge of affirming that mutations have been actually pro-

luced as a direct consequence of changed conditions, and he adds, "I do not accept mutations at all, neither as a direct consequence of changed conditions, nor spontaneously, as being sufficiently proven." The writer of the notice regrets that he should have misrepresented Dr. Sirks's opinions. The criticism arose out of passages in chap. xiv., and referred in particular to the confident narration of Tower's alleged discovery of a sensitive period in the life of a beetle, during which its germ-cells could be modified by external conditions. Dr. Sirks summarised the account in a statement which may be translated thus. "In other words: without any doubt Tower succeeded, by means of very abnormal conditions of life, in breeding from the original form *Leptinotarsa decemlineata* offspring which had lost one hereditary factor; he called these 'mutants,' the name which is generally given to forms suddenly arising which exhibit hereditary variations." Nothing could be more explicit. In continuation, however, Dr. Sirks definitely dissociates himself from the interpretation of the alleged new forms as mutants. The objection should therefore have been expressed differently. It was not the interpretation which seemed to the reviewer unfortunate or uncritical, but rather the unqualified repetition of sensational reports which, though they have attained some currency, are gravely in need of confirmation.

MESSRS. BENN BROS, Ltd., announce a new series of monographs dealing with gas and fuel. The first three volumes will be "The Administration and Finance of Gas Undertakings, with Special Reference to the Gas Regulation Act, 1920," by G. Evetts; "Gasworks Recorders," by Dr. L. Levy; and "Modern Gasworks Chemistry," by Dr. G. Weyman. The same firm will also publish shortly "Practical Optics for the Laboratory and Workshop," by B. K. Johnson, and "The Bronze Age and the Celtic World," by H. J. E. Peake.

Our Astronomical Column.

SEPTEMBER METEORS.—Though September is not a month in which any rich shower of meteors is periodically visible, a considerable number of meteors and many radiant points of moderate activity should be seen. Fireballs are also particularly abundant during the month, especially on September 13-15, and again on September 24-28. The principal systems of meteors at this time of the year radiate from Aries, Perseus, Auriga, and other constellations in that part of the heavens. At the middle of September there is usually a strong display of ϵ Perseids from $61° + 36°$; there is also a prominent shower from near α Cygni, at $314° + 48°$, and swift, streaking meteors from the Lynx frequently manifest themselves. September is, in fact, usually a productive period for the meteoric student, and further watching may reveal a somewhat rich annual display that hitherto has not received the notice it merits.

INVISIBLE SUNSPOTS.—In the year 1908 Dr. G. E. Hale published (Contributions from the Mount Wilson Solar Observatory, vol. i., No. 26) his discovery of solar vortices. This vortex hypothesis assumes that a sunspot resembles a vast tornado in which electrified particles, due to ionisation in the solar atmosphere, are rapidly whirled. The invariable presence of a magnetic field, caused by the revolving charges, confirmed this view, but it was also supported by other results of observation with the spectrograph and spectroheliograph. It was found also that most sunspots were associated in pairs of opposite magnetic polarity, and 61 and 33 per cent respectively of 970 spots were observed as bipolar and unipolar. The fact that some groups oscillated between unipolar and bipolar types, one or more small spots appearing and disappearing within the mass of calcium flocculi, suggested to him the idea of looking for invisible spots. That these might be found seemed most probable, there being vortices giving appreciable magnetic fields without any actual visible sunspots. Dr. Hale now describes his recent investigation in this direction (Proc. Nat. Acad. of Sciences, U.S.A., vol. 8, No. 7). The method he adopts is a device for rendering feeble magnetic fields visible by the Zeeman effect, and details of the procedure are given in his paper. Suffice it to say that he has found a great number of cases in which a local magnetic field was observed where no spot was recorded. He points out the importance of making systematic observations of invisible spots, especially during the periods preceding and following the visible life of those that reach maturity, in order to assist in revealing the cause of sunspot formation.

ABSOLUTE MAGNITUDES OF STARS.—Several years ago Prof. H. N. Russell produced a striking diagram of absolute magnitudes, on which the theory of giant and dwarf stars was based; it met at first with some opposition, but has gradually won its way to general acceptance. The number of stars of which trustworthy parallaxes (photographic, spectroscopic, and hypothetical) have been obtained, has now been greatly increased, and Dr. Heber D. Curtis has prepared a revised diagram, which is reproduced in the Journal of the R.A.S. of Canada for July–August. It contains 2375 stars, and shows the division into giants and dwarfs very plainly. The gap between them is complete in type M, but begins to be filled by a few stragglers in type Ko, suggesting that this may be the maximum temperature attained by stars of small mass. In types G and K the giants outnumber the dwarfs, but the reverse holds in type F. The giants here are comparatively few, but they include some of remarkable luminosity.

Broadly speaking, the regions of maximum frequency form two straight lines; that of the giants forms a horizontal line at magnitude $+1$; that of the dwarfs slopes downwards from $+1\frac{1}{2}$ at type Ao (the giants and dwarfs being here mingled) through $+5$ at type G5 (so that the sun is an average star of its type) down to 8 or 9 for Ma.

The diagram suggests to Dr. Curtis the conclusion that a sensible number of B-stars have parallaxes of the order of $0''.02$; he notes that stars of this type are being put on the working lists at the Allegheny and Leander McCormick Observatories. These stars cannot as yet be investigated for parallax by the spectroscopic method, so that the results of these measures will be awaited with interest. It will be remembered that the results have a bearing on the adopted distances of the globular clusters. The fainter the absolute magnitude found for the average B-star, the nearer we must put the clusters.

Research Items.

LAUGHTER.—In the *Fortnightly Review* for August J. A. T. Lloyd considers the problem of humour and mechanism. Bergson in his well-known study, "Le Rire," maintains the hypothesis that the essence of humour lies in the mechanisation of what ought to be spontaneous and not mechanical. The function of laughter is to punish and so to prevent the repetition of machine-like behaviour. The author of this paper criticises this point of view as being more true of Latin humour than of Anglo-Saxon and supports the theory that in the case of the latter, laughter is rather due to a feeling of superiority. He thinks, however, that recently a change has taken place, and that in Mr. Stephen Leacock's humour we approximate to humour as sensed by Bergson; he detects automata masquerading as human beings and we laugh, but not with the old laughter of superiority. A more fundamental treatment of the subject of laughter will be found in *Psyche* (vol. ii. No. 4), where Prof. McDougall develops at greater length a theory he put forward in NATURE some years ago. He believes that the theories usually advanced fail to answer the question, For what end did the human species acquire the capacity for laughter? Man is endowed naturally with the tendency to share the emotions of others, when he sees them expressed by them in action, thus rendering himself extremely susceptible to the suffering he sees around him. Were he to suffer sympathetically every pain he saw, he would very rapidly devitalise himself; hence he has developed a compensatory mechanism whereby he laughs at the pains and sufferings which are not serious or with which he can have no concern. Laughter is then primarily and fundamentally the antidote to sympathetic pain. It is necessary to distinguish laughter from the smile which is the natural expression of pleasure.

RADULA OF THE HELICINIDÆ.—This, judging from the somewhat jejune remarks concerning the method of preparation and mounting and seeming want of acquaintance with the work of earlier writers on the subject, appears to be the author's first encounter with the molluscan radula. In these circumstances, Mr. H. B. Baker (Proc. Acad. Nat. Sci. Philad. vol. lxxiv.) must be held to have acquitted himself well and has rendered a useful and well-illustrated account of the radulæ of the Helicinidæ that will prove useful to future students of the group. Although the title gives no hint of the fact, the author attempts a classification of the North American Helicinidæ largely based on the characters of the operculum, and further essays a phylogenetic scheme.

THE STRUCTURE AND BIOLOGY OF THE HOG LOUSE.—Memoir 51 of the Cornell University Agricultural Experiment Station, by Miss L. Florence, is devoted to a study of this insect and forms a carefully executed piece of morphological work. With the exception of the human louse, very few detailed studies have been made of any species of Anopleura, and the present paper fills a very noticeable hiatus. The complete life-cycle from egg to egg at a temperature of 35° C., followed out in vials worn next the body, was ascertained to require 29 to 33 days. Of this period 13-15 days was occupied by the incubation of the eggs and three ecdyses were passed through during post-embryonic life. The difficult subject of the mouth-parts is very fully discussed, but their homologies are not touched u[illegible]more particularly owing to the necessity for de[illegible]ntal studies made upon the embryo. The only investigator who has dealt, so far, with this aspect of the subject is Cholodkovsky, in his work on Pediculus. Miss Florence finds that the pharynx and mouth-parts of the hog louse are similar in plan to those of the last-mentioned insect. The result of the work, as a whole, is to emphasise the general morphological similarity of the Mallophaga and Anopleura, thereby supporting the conclusions of Mjoberg and of Harrison.

RESEARCHES ON DIPTERA.—In Bulletin No. 5 (n.s.) of the Canadian Department of Agriculture, Dr. A. E. Cameron contributes a well-illustrated paper on the structure and biology of *Simulium simile*, a small black fly infesting cattle in Saskatchewan. This insect, however, has not been observed to suck the blood of man, although it may cause mild annoyance to human beings by flying persistently around their heads. The aquatic larvæ and pupæ of this species are extensively preyed upon by a fish known as the sucker (*Catastomus commersonii*), which is proving itself one of the most successful controlling agents. As the result of experimental tests with miscible (phinotas) oil it is shown that the Simulium larvæ can be killed. The experiments, however, did not prove to be quite so satisfactory with the larvæ of *S. simile* in the river as with those of other species in a small stream. In *Bulletin of Entomological Research*, vol. 12, Part 4, Major W. S. Patton contributes revisionary notes on the genus Musca: in this first part of the paper he deals with Oriental and Australasian species. The rôle which these insects play in the dissemination of disease renders the exact determination of very closely allied species a matter of practical importance. Mr. F. W. Edwards (*Entomologist's Monthly Magazine*, July) describes a new species of Sciarid fly, *Plastosciara perniciosa*, the larvæ of which were found damaging cucumber roots and stems in a nursery at West Worthing, where they were present in very large numbers.

MANGANESE IN PLANT NUTRITION.—Since the discovery of manganese in the soil and in plant ashes by Scheele in 1774, numerous investigations have been made on the occurrence, distribution, and probable function of this element in its relation to agriculture. In the July number of the Journal of the American Chemical Society, Mr. J. S. McHargue, of the Kentucky Agricultural Experiment Station, describes a careful series of experiments, with purified materials (lack of care in this respect having caused errors in previous work), the results of which seem to point definitely to the conclusion that manganese has a function to perform in the production of chlorophyll, and consequently in carbon assimilation and possibly in the synthesis of protein.

FORMATION OF MARINE DEPOSITS ABOVE SEA-LEVEL.—The Report of the Secretary of the Smithsonian Institution for 1921 quotes some observations made by Dr. Paul Bartsch at the south-east point of Hanouma Bay, Hawaii, where he found a marine flora and fauna living at a considerable elevation (the precise height not given) above the level of the sea. Algæ, molluscs, crustaceans, echinoderms, and other marine organisms, says Dr. Bartsch, "occupy pools and puddles kept moist and supplied with fresh water by the spray from the breaking surf, which incessantly pounds that shore. I consider this an important observation, since the occurrence of fossiliferous laminæ bearing marine organisms between sheets of lava has been held to indicate that they

were deposited at or below sea-level, and their occurrence above this has been held as evidence of elevation. We have here an instance which indicates that this is not necessarily the case, for such a lamina would be produced if a new outpouring of lava were to cover up the place mentioned."

CAINOZOIC FISHES OF CALIFORNIA.—In a paper on the fossil fishes of the diatom beds of Lompoc, California (Leland Stanford Junior University Publications, 1920), David Starr Jordan and James Zacchens Gilbert direct attention to beds of Miocene age, probably formed in a quiet, shallow, marine bay; they are rich in large diatoms and "heavy" radiolaria. At one special horizon an extinct herring, *Xyne grex*, is represented by an immense number of individuals, all adult, all about six inches long, and unmixed with any other fish. They appear to have entered the bay with the view of spawning, and to have been killed suddenly "with no evidence of agony or distortion." In a subsequent paper, on "The Fish Fauna of the California Tertiary" (Stanford Univ. Publications, Biol. Sci., vol. 1 No. 4, 1921), Dr. Jordan gives very interesting restorations of a number of fossil fish in a series of captivating plates, preceded by photographs of their skeletons. He refers again to the remarkable shoal of herring, which provides 8 or 10 specimens to the square foot over an area of four square miles. It is estimated that 1200 million individuals perished on this one occasion. Though it is said that Dr. Mann has offered an explanation, we are unable to trace it in these memoirs.

CARBON-BLACK IN THE UNITED STATES.—Recent articles in NATURE have directed attention to the various products obtainable from natural gas, among which petroleum, allied light oils, and helium figure prominently. An important industry also exists for the purpose of manufacturing carbon-black from this source, this product forming the basis of such commodities as printers' ink, paints, varnishes, polishes, cement colours, etc. It is also considerably used in the rubber industry for increasing the resiliency and toughness of rubber tyres. The processes of extraction of carbon-black from natural gas are confined principally to the United States, Louisiana being the leading state in this respect, the other producing states being West Virginia, Kentucky, Oklahoma, Pennsylvania, Montana, and Wyoming. The industry thrives best where there is an abundant supply of natural gas available in fields sufficiently isolated as to inhibit the use of the gas for domestic purposes. The yield of carbon-black per thousand cubic feet of gas ranges from 0·2 lbs. to 3·5 lbs., and in 1921 more than 31 million pounds were produced by Louisiana alone, the average yield being 0·97 lbs. per m. cub. feet. The total production for the United States for that year amounted to 50,766,315 lbs., valued at 5½ million dollars (E. G. Sievers, Min. Resources Unit. States, 1921, pt. ii. p. 33). Recent legislation in some states, in particular Louisiana, has tended to check the progress of this industry, since the rapid advancement of natural gas gasoline manufacture (a far more valuable product) has resulted in the conservation of natural gas for that purpose. Operators are therefore compelled to extract the gasoline from the gas before the latter is burned in the carbon-black plants. In some cases this has served to eliminate the industry altogether, but by adapting and by using the gasoline and carbon-black plants in conjunction, such calamity can be, and is being, fortunately avoided.

THE COURSE OF PHOTOGRAPHIC DEVELOPMENT.—Forty-five years ago, Abney (*Phil. Mag.*, 1877) coated exposed plates with a second sensitive film before development. After development he stripped off the second film and found that a part of the image was in it—that is, the development had spread from the exposed to the unexposed sensitive material. On the contrary, common experience with gelatine plates shows conclusively that when the exposure is insufficient it is impossible to develop an image of the maximum density that the plate can yield. If development spreads at all from exposed to unexposed particles, the spreading effect must be very limited. Recently, this matter has been investigated in the modern, microscopical manner, by tracing the changes in the particles themselves. Prof. The Svedberg has shown that developability is not conferred by developable grains upon contiguous grains, and that the percentage of grains developed is not increased when the grains are "closely packed together." In the September number of the Journal of the Royal Photographic Society, Messrs. A. P. H. Trivelli, F. L. Righter, and S. E. Sheppard, of the Research Laboratory of the Eastman Kodak Company, give details of their experiments, which show that where a group of two or more grains forms a "clump," this clump develops as a unit, and if only one of the constituent grains has been made developable, the whole group is completely developable. They used Svedberg's methods. They consider that Svedberg's results are conclusive evidence that developability in his case was not transferred from one grain to another, and ascribe their apparently contradictory results to the character of the emulsion. Svedberg used a special emulsion with mostly spherical grains of nearly uniform size, while the authors' emulsion had a wide range of grain sizes and contained many large polyhedral tablets. Obviously this matter is of fundamental importance from a theoretical point of view.

UPPER AIR RESEARCH.—Part I. of an aerological survey of the United States, the results of observations by means of kites, by Mr. W. R. Gregg, is published as Supplement No. 20, U.S. *Monthly Weather Review*. An abstract by the author is also given in the *Monthly Weather Review* for May last. The object of the discussion is to furnish results so much needed at the present time in connexion with aviation and ordnance. Much detailed information can be obtained from the numerous tables and diagrams as to the characteristics of the free air over the United States east of the Rocky Mountains. Kite observations are made at six stations established by the Weather Bureau during the period 1915 to 1918, and there are data from other sources. Various meteorological results for the upper air are given for the several months, the season, and the year. The values at Blue Hill, Mass., and Mount Weather, Va., each based on a long series of observations with kites, are included in the discussion. Free-air results will augment the general knowledge of atmospheric circulation, and of the movements of cyclones and anticyclones. It is rightly claimed that they will give information of value in connexion with the laying out of a permanent flying course or "air-way." Near the surface the turning of the winds is generally to the right, and the deviation is greater in winter than in summer; moreover, it is greater at northern than at southern stations. The average wind velocity at lower levels increases most above surface south-easterly to south-westerly winds, but at greater heights the largest increases are found above surface south-westerly to north-westerly winds. The velocities are least in all seasons and at all heights above surface north-easterly to east-south-easterly winds. A review of pilot-balloon observations is foreshadowed at a future date.

Einstein's Theories.

THE *Revue Philosophique* (Alcan, Paris), edited by Prof. Lévy-Bruhl, has just issued (July-August) a special number devoted to the consideration of Einstein's theories of relativity. It consists of four articles of exceptional ability and importance, all directed to the philosophical aspects of the problem. That Einstein's theory is established, in the meaning that it is applicable in physical science, is accepted by each of the writers, and their aim is to decide how far it forces upon us a new way of thinking about physical reality

The first article is a translation by M Léon Bloch from the German of Hans Reichenbach, " La signification philosophique de la théorie de la relativité " The philosophical interest centres on the concept of time. Must we give up the absolute meaning of simultaneity? If we do, the Michelson-Morley experiment at once ceases to be incomprehensible, light *can* have the same velocity in the moving system which it has in the system at rest But can we give up absolute simultaneity without being involved in logical difficulties and finding ourselves confronted with a pure paradox? In a very skilful argument the writer concludes that we can and that we must Relativity is both a logical necessity and an experimental fact This leads to the consideration of the part played by the velocity of light in Einstein's theory.

In Nature the electromagnetic waves play a unique part and are of greater importance than any other phenomenon which serves us as a signal They alone (if we set aside gravitation) transmit an action across empty space Now as the forces which the individual particles of matter exercise on one another are of the same nature as electromagnetic forces, it follows that all propagation of material action resolves itself ultimately into an electrical transmission

The essential ideas of the theory of relativity were forestalled by Ernst Mach forty years ago, and Einstein is continually reminding us of our indebtedness to him The idea that movement as a spatial phenomenon can be recognised only in relation to other bodies was much older—we have it, for example, in Descartes and in Leibniz—but what distinguishes Mach's point of view is the idea that movement must have not only kinematic but also dynamic relativity, that what we call the forces of inertia must be bound up with the presence of other bodies In Mach, however, the relativity of theory of knowledge is not distinguished from physical relativity; it remained for Einstein to show that the actions of movements, or what we name forces, can be reduced to a difference between the distributions of masses

The second article, by M. G. Cerf, " Pour l'intelligence de la relativité," deals particularly with the exact meaning we are to give to the terms employed in the theory, and the writer draws largely on the works of Henri Poincaré.

The third article, "Einstein et la métaphysique," is by M. Edmond Goblot, the distinguished logician and philologist. He finds considerable amusement and no little instruction in the popularisers of Einstein, more especially those who competed for the Higgins prize of the *Scientific American* Publishing Co In his conclusion he says: " Je résume et précise ma question. Einstein est-il mathématicien, physicien ou métaphysicien? Mathématicien il l'est Physicien il l'est aussi. S'est-il borné à cela, ou s'est-il abandonné aux débauches de métaphysique inconscient qu'on nous fait lire en son nom? Dans les deux cas, il est grand temps d'exorciser tous ces fantômes "

The fourth and concluding article, by M Richard-Foy, " Le temps et l'espace du commun sens," is a very clear statement of the whole problem to meet which the new principle is required. It deals mainly and sympathetically with M Painlevé's protest against the refusal to allow any place for the concept of an absolute in physics. The rejection of time and space as absolutes is not irreconcilable, he argues, with such a position To say that time, space, and movement are not absolutes means that, instead of being realities which impose their laws on phenomena, they are only abstractions, necessary to express those laws, but capable of assuming the most diverse forms. We choose among these forms with the simple aim of discovering the most convenient, but our choice has limits For example, we cannot define simultaneity in any two points absolutely, yet we must define it so that it is not possible that my friend has read my letter to him before I have written it.

Educational Work of the Ministry of Agriculture.

THE Intelligence Department of the Ministry of Agriculture and Fisheries has issued a Report on the work of the department for the years 1919-1921, which is published at the price of 5s by H.M. Stationery Office The duties of this department are concerned with agricultural education, agricultural research, the agricultural training of ex-officers and men, horticulture, the improvement of live-stock, the destruction of rats, and the diseases of animals.

Agricultural education is provided through the agency of colleges, including agricultural departments of universities, and by farm institutes, local classes, and lectures. The first group comprises eleven institutions, of which all, except the Harper Adams, the Midland Agricultural College, the University College, Reading, and the Seale Hayne College, are connected with universities in which students may obtain a degree with agricultural science as their chief subject. In most cases the agricultural department is actually part of the university organisation, and it is recognised that in many respects this is an ideal arrangement Agricultural students thereby obtain the intellectual stimulus that is associated with intercourse with students in other faculties Future teachers, scientific workers, and agricultural experts all gain by the indefinable atmosphere which pervades a university course On the other hand, it has been found that although, theoretically, expenditure should be saved by taking advantage of the courses in general science which a university provides, in actual practice it has proved necessary to provide special teaching even in preliminary scientific subjects designed for agricultural students

By means of this special teaching an agricultural flavour is imparted to chemistry, botany, zoology, or whatever the fundamental science may be, and thus from the very beginning the student's interests are awakened and stimulated. Against such an arrange-

ment it has been urged that association with other students tends to divert a certain number of agricultural men to other subjects. But it is probable that an agricultural department of a university tends to attract more men than it loses. The courses provided in university departments of agriculture are intended for the education of future landowners, land agents, and large farmers, but for investigators it is found best that they should pass through an honours school in pure science before taking up the study of the application of science to agriculture. The report lays special emphasis on the need for the study of accountancy, which in its application to costs of production may be a powerful instrument in determining the economic success of a farm.

It is pointed out that the cost of providing the necessary staffs in a university or college is now so great that it is impossible for each college to provide highly specialised instruction in every branch of agricultural education, but that extreme specialisation must be left to individual colleges. Again, tutorial instruction and encouragement of private reading are urged as a means of relieving pressure on formal lectures, and so of keeping down expenses.

While agricultural departments in universities and agricultural colleges are the agency of providing instruction to prospective landowners, large farmers, and public servants, the needs of the ordinary farmer's son are best supplied through farm institutes. The latter have been developed in recent years as the result of the recommendations of Lord Reay's Committee which in 1905 strongly urged their creation. These farm institutes are under the authority of County Councils, directed by the Ministry of Agriculture. An agricultural education committee having been set up, it submits its scheme to the ministry, and this, if approved, is supported by grants. The staff of an institute consists in most cases of an organiser, a director of agriculture, and certain teachers. The county organiser is usually the head of the farm institute, and towards his salary the ministry may contribute as much as four-fifths. It also pays annual grants up to two-thirds of the total general expenditure. Classes are provided as a rule for twenty-four weeks during winter, at a time, namely, when young farmers can leave their farms and devote their time to study. While a certain amount of manual training is possible at farm institutes, it is recognised that the best place for getting such instruction is on the farm of the student's father. The teaching of science is in close contact with practice, and is concerned principally with such subjects as varieties of crops, methods of cultivation, rotations, manures and feeding stuffs, principles of feeding and breeding, dairying, poultry, and farm book-keeping. Such farm institutes have been established in Cumberland, Essex, Hampshire, Carnarvonshire, Monmouthshire, Cheshire, Hertfordshire, Northamptonshire, Somerset, Staffordshire, Suffolk, and Denbigh, while others are contemplated in Durham, Kent, Carmarthen, West Sussex, and the Holland Division of Lincolnshire.

Besides providing instruction for students, the colleges and institutes are intended to serve as advisory centres for farmers generally. Such advisory officers are usually specialists in plant pathology, botany, chemistry, and general agriculture, and to these farmers are encouraged to turn in case of difficulty. This they are doing in increasing numbers every year, and one of the most gratifying features of the present position is the disappearance of prejudice on the part of cultivators to education and science.

University and Educational Intelligence.

ABERDEEN.—Mr. G. P. Thomson, lecturer in mathematics at Corpus Christi College, Cambridge, has been appointed professor of natural philosophy in succession to Prof. C. Niven, who has retired.

LEEDS.—The honorary degree of Doctor of Science has been awarded to Prof. A. F. Holleman, of the University of Amsterdam.

PROF. CHARLES CROWTHER has been appointed Principal of the Harper-Adams Agricultural College, Newport, Salop, in succession to Mr. P. Hedworth Foulkes, who has been Principal since the College opened in 1900.

AN important conference of representatives of British and Swiss universities took place at Basle last month. There were present fifteen delegates from Great Britain and Ireland, Oxford being represented by the Vice-Chancellor and the Warden of All Souls, Manchester by the Vice-Chancellor and Prof. T. F. Tout, Edinburgh by Sir Richard Lodge and Prof. J. Mackinnon, and Birmingham, Bristol, Cambridge, Leeds, London, Wales, St. Andrews, Dublin, and the National University of Ireland each by one delegate. Each of the seven Swiss cantonal universities was represented. At the three formal sessions of the conference, held on August 22 and 23 in the great hall of the University, the topics of discussion were the recognition by the British universities of university entrance examinations passed, university studies pursued, and degrees conferred in Switzerland, and *vice versa*, and interchange of university teachers. Of perhaps even greater importance than the formal discussions were the conversations for which ample opportunities were provided in the course of the numerous social functions at which the visitors were entertained. The Federal Ecole Polytechnique of Zurich was unfortunately not represented at the conference. Before the war this institution, like the cantonal universities, drew a large proportion of its students from other countries where economic conditions are at present unfavourable to the migration of students to Switzerland. Consequently there are plenty of vacant places in its laboratories, which are well equipped for advanced work in, for example, industrial chemistry and electrical engineering.

A PROVISIONAL programme has been issued by the Sociological Society, Leplay House, 65 Belgrave Road, Westminster, S.W.1, of a conference on the correlation of the social sciences, which it is proposed to hold at Oxford on October 7-9. The conference will not be open to the public, but invitations are being issued to members of the Sociological Society and to representatives of the social sciences from the universities of Great Britain. The object of the conference is to provide an opportunity for the discussion by specialists of various branches of social science with the view of co-ordination. Mr. F. S. Marvin (history), Sir Halford Mackinder (geography), Mr. Julian Huxley (biology), Prof. C. E. Spearman (psychology), Prof. L. T. Hobhouse (philosophy), Dr. R. R. Marett (anthropology), Prof. J. E. G. de Montmorency (law), and the Rev. A. J. Carlyle (political science), will probably address the conference, dealing with the various aspects of sociology named.

Calendar of Industrial Pioneers.

September 17, 1823. Abraham Louis Breguet died. — The foremost horologist of his day, Breguet was born in Switzerland in 1747, but at an early age removed to Paris, where he became a member of the Bureau des Longitudes and of the National Institute. He is remembered for his improvements in the escapement of watches and his invention of the sympathetic pendulum and of a sensitive metallic thermometer.

September 17, 1869. John Elder died.—One of the greatest marine engineers, Elder was trained under his father, David Elder, at Napiers'. In 1852, at the age of twenty-eight, he joined the engineering firm of Randolph Elliott and Co. and became the virtual founder of the great firm at Govan known since 1886 as the Fairfield Shipbuilding and Engineering Co. He was one of the first engineers to grasp the importance of the new science of thermodynamics, and he successfully introduced the use of the compound engine at sea, thereby effecting a saving of 30 to 40 per cent. of the coal burnt. The Elder chairs of naval architecture at Glasgow and at Liverpool were founded respectively by his widow and his brother Alexander, who died in 1915.

September 17, 1895. Johann Sigismund Schuckert died.—After working as a mechanic in various towns of Germany, Schuckert spent some years in America, where he became acquainted with Edison, and on his return home, in 1873, set up a workshop at Nürnberg. He then began the manufacture of dynamos and other electrical machinery, and became one of the best-known electrical engineers in Germany.

September 18, 1860. Joseph Locke died. Born near Sheffield in 1805, Locke gained his first experience of railway engineering under George Stephenson on the Manchester and Liverpool Railway. Afterwards by himself, or with his partner Errington, he built many of the early railways, including those between Manchester and Sheffield, and London and Southampton, and the line from Paris to Rouen and Havre. His railways were notable for the absence of great and expensive works. From 1857 till his death he was President of the Institution of Civil Engineers.

September 19, 1899. Leon Bourdelles died. An engineer of the Corps des Ponts et Chaussées, Bourdelles rose to be head of the Lighthouse Department, in which situation, by the display of uncommon energy and resource, he revolutionised the lighting of the French coast, increasing the aggregate candle-power from 1,000,000 to nearly 100,000,000 without increasing the annual cost.

September 20, 1885. Walter Weldon died.—The son of a Loughborough manufacturer, Weldon became a journalist in London. Turning his attention to practical chemistry, he sought means of recovering the manganese peroxide used in the manufacture of chlorine, and about 1868 patented the lime-manganese process, which reduced the cost of bleaching powder by 6*l*. a ton and added something like 750,000*l*. per annum to the national wealth.

September 22, 1852. William Tierney Clark died.—A well-known civil engineer, Clark for forty years was engineer to the Middlesex Water Works. His masterpiece was the great bridge erected across the Danube at Budapest in 1839-49 at a cost of 622,000*l*.

September 23, 1878. John Penn died.—For many years Penn was the leading marine engine builder on the Thames. He invented the lignum vitæ stern bush bearing for screw ships, and during the Crimea War he organised the manufacture of the engines for gunboats, completing 90 sets of engines of 60 n.h.p. each in ninety days, the first example of mass production of machinery for warships. E. C. S.

Societies and Academies.

PARIS

Academy of Sciences, August 16.—M. Émile Roux in the chair.—M. de **Sparre**: Remarks on the depressions resulting from a breakage in a water main under pressure.—Kyrille **Popoff**: The integration of the equations of ballistics under general conditions of resistance.—Pierre **Auger** and Francis **Perrin**: The shocks between α-particles and atomic nuclei. An application of a modification of C. T. R. Wilson's method of studying the paths of α-rays. Photographs of the paths were taken with two cameras at right angles to each other, and details of results in argon and in hydrogen are given. For argon the value of the atomic number calculated from the results of the observations is 19 (instead of 18).—I. Newton **Kugelmass**: A new apparatus, the nephelectrometer. The change in the transparency of a colloidal solution is measured by the deflection of a millivoltmeter connected with a thermocouple. The light from an electric lamp, after passing through a cell containing distilled water, is allowed to fall on the thermocouple for a fixed time, and the deflection of the millivoltmeter measured (I). The water is then replaced by the colloidal solution and the deflection (I') measured under the same conditions. The ratio I'/I gives the transparency index.—A. **Marcelin**: Measurement of the pressure of "superficial fluids." Detailed study of oleic acid.—F. **Granel**: The morphological signification of the pseudobranch of the teleosteans.

The Supply of Petroleum Products.

MR. SYDNEY BROOKS contributes to the *Fortnightly Review* for September 1 an article entitled "A British Oil Victory," from which the reader might at first infer the discovery of a large British oilfield or at least a sudden remarkable flow from the Hardstoft well in Derbyshire. Nothing quite so startling has happened, however; Mr. Brooks's "victory" is of a far less sensational character, being, in fact, the opening of the Anglo-Persian Oil Company's refinery at Llandarcy, Swansea. The author regards this event as the *pièce de résistance* of a series of British achievements in the "international war of industry," and mentions in the same breath the opening of the Manchester Ship Canal Oil-Dock, the discovery of oil in Papua, and the securing by a British Company of the oil rights of Macedonia.

It seems a pity to have to disillusion Mr. Brooks and his readers, but while one admires his natural pride in British commercial successes, and also the patriotic zeal with which he writes, there is in his article an optimism apparently born of an inadequate knowledge of the facts and a clouded sense of proportion. The Llandarcy refinery is admittedly a sound industrial proposition for this country, but one can scarcely recognise yet in its existence a really serious competitor with the Shell or Anglo-American Oil Companies' interests, as Mr. Brooks suggests. Even if the Anglo-Persian Oil Company agreed to distribute their petroleum products solely in the British Isles, this would only represent a relatively small percentage of the total annual consumption of such commodities in this country. The bulk of imports of petroleum products come from the United States and Mexico; they are controlled by the Dutch and American organisations referred to and together constitute more than twenty-five times the amount of such products obtained from Persia, based on recent statistics of production and importation.

There is always the possibility—indeed, the probability—that the Anglo-Persian Oil Company's interests will expand considerably in the next few years, but a refinery, however large and well-equipped, is dependent on an abundant supply of crude oil, and this must come to us from overseas. So long as the United States and Mexico together produce more than 85 per cent of the world's supply of crude petroleum, so long shall we be dependent on those countries and their representatives for the bulk of our supplies of petroleum products.

The construction of the Llandarcy refinery is indeed an industrial event of no mean importance, but at least let us preserve a clear perspective in the matter. The

Manchester Ship Canal Oil-Dock should be hailed rather as an engineering feat than an "oil victory"; without plenty of imported oil the dock ceases to exist as such. The strike of oil in Papua is not surprising; both in British and former German territory oil occurrences have long been known; geological surveys have been made and the oil sampled, but the technical difficulties, an appalling climate and the native labour troubles involved, have retarded development, even if oil exists in commercial quantity—yet a moot point. Then the Macedonian concessions are, geologically speaking, even more doubtful than Papua as regards oil potentialities: their securance may have been a political or commercial *coup*, but as an incident in the "British Oil Victory," it was neither heroic nor decisive.

We suggest to Mr. Brooks that in the general appreciation of the above facts lies the reason of apparent public indifference to the erection of the Llandarcy refinery; the matter was neither ignored nor its significance missed, as he complains, it is simply that to the average man this and kindred propositions appeal as ordinary extensions to business, and where oil is concerned especially, judgment by results rather than hasty optimism at the beginning is the safer policy.

H. B. M.

The Ways of Insects.

The Psychic Life of Insects. By Prof. E. L Bouvier. Translated by Dr. L. O. Howard. Pp. xvii+377. (London: T. Fisher Unwin, Ltd., 1922.) 8*s.* 6*d.* net.

THIS is, we think, the most reasonable book that has been written on insect behaviour as a whole. It is scholarly and critical; it avoids extremes; and it leaves open questions open. There is, as every one recognises, an inclined plane of insect behaviour. On the lowest level there are tropistic activities (the translator's term "tropic" will not do), when the insect makes towards or away from the light, against the stream or the wind, towards or away from an odour, and so on. In everyday life these tropisms count for much. They are obligatory constitutional automatisms; they are induced by asymmetry of stimulus which provokes asymmetry of muscular activity; and this automatically restores physiological equilibrium. Interesting situations arise when one tropism (*e.g.* in relation to light) influences or counteracts another (*e.g.* in relation to gravity); and it is also noteworthy that a tropism may change its character with the age or physiological state of the organism.

Then we have to recognise internal rhythms which are enregistered in the insect's constitution and imply a certain organic memory. Very suggestive is Roubaud's case of the African "house-worms" (maggots of *Auchmeromyia luteola*) which burrow in the earthen floor of the hut during the day, but come up at night to gorge themselves on the blood of the prostrate sleepers. For Roubaud has proved that these larvæ experimentally treated can be induced to remain awake during the day. The rhythm is constitutional, but its punctuation is environmental.

Bouvier passes to the phenomena of "differential sensitiveness"—a term which never strikes us as very luminous. When a bed-bug, which naturally seeks darkness, is suddenly illumined, its typical behaviour is to turn through 180 degrees and proceed in the opposite direction. Insects avoid situations or postures which are contradictory to the exercise of their normal tropisms; but their behaviour is automatic, not voluntary. Moreover, the reversal of the movement in relation to a particular stimulus, say light, may be induced by a sudden change in some other stimulation, *e.g.* by a gust of wind or a warm breath The familiar phenomena of "catalepsy" or "feigning death" *in insects* are regarded as exaggerations of "differential sensitiveness," and the author is very sceptical as to utilitarian interpretations.

So far there is no appreciable psychical note. That is not struck till we find the insect selecting one reaction rather than another, profiting by experience in a simple way, and showing individual as contrasted with organic memory. Some very interesting examples are given of an individual change of habit in novel circumstances. The intelligent adjustment of habits has played an important part in the evolution of instinctive behaviour, for insects have "the power very quickly to transform acts which are intelligent at first into automatic acts."

Bouvier's position in regard to instinctive behaviour is eclectic. There is no special faculty of "instinct," and the various forms of instinctive behaviour are not all on the same level nor of the same origin; some may have arisen as germinal mutations (which will be afterwards tested in everyday life), while others may have arisen in the course of intelligent apprenticeship. "In an intelligent way, new habits are established, which by heredity are added to the patrimony of instinct, modifying it and forming one of the essential elements of its evolution." "It is probable that all the higher instincts had originally this intellectual quality." And yet Bouvier agrees with Bergson that instinctive behaviour is on a different tack from intelligent behaviour; they help one another; they are both "opposites and complements."

It is likely enough that Bouvier is right in believing that instinctive behaviour is manifold, and that it may be established as an innate capacity in more than one

way. It is too soon to expect clear-cut conclusions in regard to these questions. But many will agree with the author in regard to the following three points. (1) There is in instinctive behaviour a psychical awareness as well as a physiological concatenation. "One can hardly see in insects simple reflex machines, for they know how to bend to circumstances, to acquire new habits, to learn and to retain, to show discernment. They are, one can say, somnambulists whose minds awaken and give proof of intellect when there is need for it. This takes us a long distance from the mechanism of which Bethe has made himself a protagonist." (2) Whether a capacity for novel instinctive behaviour originated from a sudden mutation or as the outcome of a more or less slow modification of habit, there must always be a period of individual apprenticeship, when the new card is played, or when the new adjustment is tested for what it is worth. (3) The climax of instinctive behaviour among arthropods is correlated with their characteristic organisation—a non-living armature of chitin with the musculature inside, not outside, and a considerable number of specialised appendages, which must be used in one way and in no other. "The appendages of Arthropods are nearly unchangeable in the individual and are narrowly adapted to certain purposes; they are the tools for instinctive work, thus differing from the less specialised but more supple limbs that serve as implements to the vertebrates, at least to the higher vertebrates." The contrast between a bee's specialised proboscis and a man's generalised hand is diagrammatic. So from the beginning, as Bergson also suggested, insects "were bound to use these organic tools, and they made the best use of them. Their main psychical task was to grave upon their memory and to repeat instinctively the acts to which these organs were fitted."

The fundamental part of Bouvier's masterly book is devoted to the analysis of the inclined plane of insect behaviour. He goes on to special problems such as the relation of insects to flowers, the faculty of orientation, the social life of insects, and the division of labour in nest-making Hymenoptera. Apart from a few slips, the translation, which cannot have been easy, is an effective piece of work.

Chemistry of the Plant Cell.

Chemie der Pflanzenzelle. By Prof. Dr. Victor Grafe. Pp. viii + 421. (Berlin: Gebrüder Borntraeger, 1922.) 105 marks.

THE title of this book raises immediately the interesting question as to whether the chemistry of the plant cell can yet be made the subject of a text-book. A perusal of this book leaves no doubt that such a work has still to be written. There are many interesting pages, but the book is in no sense an introduction to the special chemical metabolism proceeding within the plant cell.

The author treats his subject mainly from the point of view of physical chemistry, and the reader must, if the book is to be read with profit, be very thoroughly grounded in organic chemistry and bio-chemistry. Thus an interesting section on the cell wall, and a final subsection dealing with the chemistry of photosynthesis, are not accompanied by any discussion of the chemistry of the carbohydrates. Again, in a section of some 150 pages under the general title of protoplasm, ten pages only are assigned to the chemistry of lipoids (fats, phosphatides, sterols, etc.), proteins and nucleo-proteins; the same section closes with a subsection of some thirty pages, devoted to the pigments of the plant, which deal mainly with the recent researches of Willstatter upon the leaf pigments and the anthocyanins.

Lack of proportion is manifest throughout the book, and is accompanied by a lack of arrangement which leads to much tedious repetition. The main topics, diffusion, osmosis, plasma permeability, colloids, and adsorption, with which the book opens, recur again and again throughout its pages. Thus a later subsection headed plasma structure, in the section upon protoplasm, consists mainly of a rediscussion of the phenomena of plasmolysis and permeability. Undoubtedly these topics are of primary importance in a work upon plant physiology, but it is doubtful whether their significance in this field will be better apprehended as a result of the study of this book. The discussion of the physical chemistry of these complex phenomena is far too brief and inadequate to form a sound critical basis for their subsequent application to the still more complex problems of the living cell

To cite specific cases: the first examples of adsorption phenomena dealt with, freely assume the specific adsorption of one ion from the solution of an electrolyte with consequent change in the reaction of the solution. The work of Baumann and Gully, and of Wieler, is cited in this connexion, and only upon a later recurrence of the topic is Sven Oden referred to in a footnote. Reference to Sven Oden's papers will show how unsound is the experimental basis for this assumption of specific ionic adsorption, while recent discussions by Bancroft ("Applied Colloid Chemistry," 1921) and E. A. Fisher ("Physico-Chemical Problems relating to the Soil," Faraday Society, 1922) show how inadequate are discussions of adsorption phenomena, based, as this one is, upon the application of Gibb's theorem

without further reference to the chemical questions involved.

Again, a brief discussion of the Liesegang rings obtained when silver nitrate diffuses into gelatin containing potassium bichromate (p. 43), is made the starting-point for many suggestions as to the significance of these phenomena in explaining stratification in structural features of the cell and even of tissues. In view of our lack of information as to these diffusion phenomena, little significance can attach at present to the analogous appearances in cell structures referred to by the author.

The physical properties of protein sols and gels are discussed without reference to the reaction of the solution or the iso-electric point of the protein, the fundamental papers published by Jacques Loeb being ignored. Swelling and imbibition remain, therefore, very incompletely treated, and the interesting American work upon the importance of pentosans in the retention of water by plant mucilages is also neglected. The author refers, however, in his preface to the continued post-war difficulty in obtaining access to foreign literature, and doubtless these sections will undergo modification in a later edition.

The subsection upon enzyme action shows a similar lack of arrangement. It is to be hoped that the author's endorsement of Euler's suggestion that when enzymes are active as catalysts during synthesis they should be denoted by the suffix "*ese*," will not lead to an extension of the practice. His discussion of enzymes in relation to metabolic synthesis is unsatisfactory, but it at least makes clear how little reason there is for such a practice. Without a clear discussion of modern views of the stereo-chemistry of the hexoses, the discussion of the catalytic action of maltase and emulsin during synthesis is necessarily difficult, but it is curious to find no mention of the experiments of Bourquelot and Bridel, which had reached an interesting stage even in pre-war days. An interesting discussion of the action of hormones in relation to stimulus and response appears in this subsection upon enzymes. The subject reappears in a later section under the heading of response to stimulus, and here reference is made to the work of Paal, Ricca, and others, the absence of which in the earlier discussion had aroused surprise.

The attempt made to base the phenomena of stimulus and response upon physico-chemical phenomena provides some of the most interesting reading of the book, but it would appear hopeless to expect success in such an effort when the subject of the quantitative study of growth rate is compressed into less than two pages at the end of this section.

Scientific Management of Farming.

(1) *Farm Management: A Text-book for Student, Investigator, and Investor.* By Prof. R. L. Adams. (Agricultural and Biological Publications.) Pp. xx+671. (New York and London: McGraw-Hill Book Co., Inc., 1921.) 20*s*.

(2) *Organised Produce Markets.* By Prof. John George Smith. Pp. ix+238. (London: Longmans, Green and Co., 1922.) 12*s*. 6*d*. net.

(3) *Agricultural Co-operation in England and Wales.* By W. H. Warman. Pp. xi+204. (London: Williams and Norgate, 1922.) 5*s*. net.

(4) *Rural Organization.* By Prof. W. Burr. Pp. xiv+250. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1921.) 12*s*. net.

THE volumes before us emphasise the fact that farming involves two distinct kinds of operation, the production of crops and animals, and the marketing of the resulting commodities. Scientific investigators have in the past confined themselves almost exclusively to production, this being the side that involves the soil, the growing plant and the living animal, and with these almost all the sciences at present studied; it is quite evident, however, that there is a wide field for the economist in the marketing problems that will amply repay study.

(1) Prof. R. L. Adams deals exclusively with American conditions; his book is of a type that is not produced in this country, the old Fream in the past and some of the Oxford publications in the present being our nearest approach to it. It covers the whole range of the farm activities, largely from the economic side, but with constant references to modern improvements in production and the scientific principles on which they are based.

A great advantage of the book is the generous provision of tables of data showing crop yields, costs of production, effects of various factors on costs, on income, etc., with references to the original sources which will be at least equally appreciated. It is these data and references which give the book a special value to the teacher in this country, for he is thus enabled to ascertain how the values have been arrived at and how far they can help him in his work.

(2) Prof. J. G. Smith, of the Faculty of Commerce in the University of Birmingham, sets out in his book the general characteristics of organised markets and the broad principles involved in marketing operations. Considerable space is devoted to wheat and large-scale buying operations are discussed in detail. The volume is of interest as showing the extraordinary complexity of the processes whereby wheat is transferred from the Canadian farm to the English consumer,

(3) Major Watman deals more narrowly with the agriculturist and is concerned with an account of agricultural co-operation in England and Wales. He is convinced that co-operation is essential to the success of agriculture, and he is able to show that it is beginning to take hold on the rural community. Examples are given of farming societies, egg societies, dairy societies, etc., which are doing good work and have an undoubted future: we should, however, like to have seen some tables showing the amounts of produce handled, the financial turnover, etc. It may be the amounts are not large, but it is desirable that the data should be published.

(4) Prof. W. Burr discusses a wider problem, the organisation of the whole rural community in contradistinction to the urban population. It is widely recognised by American writers that the urban and rural communities are distinct, having different needs and requiring different methods of organisation. In this country the rural organisation has grown up through long ages and the urban population is the new problem: in America, however, the rural community is also new, and experts are studying closely the method in which it has developed, and feeling their way to some new organisation. The book is written for students, and it includes lists of questions and "research problems," which space, however, might usefully have been devoted to references to help those who wish to pursue the study of this interesting subject.

An Ideal Text-book of Physics.

Cours de physique générale à l'usage des candidats au certificat de Physique générale, au diplôme d'Ingénieur-Électricien et à l'Agrégation des Sciences physiques. Par Prof. H. Ollivier. Tome Second: Thermodynamique et Étude de l'Énergie rayonnante. Deuxième édition, entièrement refondue. Pp. 415. (Paris: J Hermann, 1922.) 28 francs net.

FEW examination candidates are likely to base their studies on a book in a foreign language adapted to foreign courses; and it is therefore unnecessary to consider here the merits of this work for the purpose for which it is primarily intended. It will suffice to say that none but the ablest students could master it unaided. But as an exposition of the fundamental propositions of mathematical physics, from which those of us who have passed the examination stage may refresh our memories concerning what we once knew, or were officially credited with knowing, the volume exhausts our vocabulary of praise. There are no native works which profess to cover the same range, and few of any merit which cover part of it. We usually rely on Winkelmann or Chwolson. The former is far more encyclopædic, the latter more experimental; for M. Ollivier gives very few references and only such experimental facts as are necessary to illustrate principles; but in conciseness, lucidity and accuracy they are not to be mentioned in the same breath with our author. Even in completeness he is sometimes superior, for he enters more fully than most authors into some interesting byways of physics, such as luminescence, photometry and astrophysics.

The treatment is at once original and conservative. The order of historical development is usually abandoned completely and the subject developed in the full light of our present knowledge. Consequently, the science is presented deductively rather than inductively, the most general principles being stated first and their most important logical consequences (which are of course really their basis) gradually worked out. Whether this reversal of the usual sequence is desirable in teaching may perhaps be questioned, but there is no doubt of its efficacy in summarisation. On the other hand, there are no signs of the modern tendency to seek principles so broad and far-reaching that in gaining generality they almost lose physical significance. Thus the Boltzmann conception of entropy as probability appears only towards the end of the exposition of thermodynamics and the Nernst theorem appears mainly in foot-notes. But there is nothing old-fashioned about the book; if the author does not always pay so much attention as some would wish to the latest work, the reason is clearly a deliberate judgment of value and not mere ignorance.

But M. Ollivier's supreme merit in our eyes is that he really does write about mathematical physics. He does not give us either a treatise on pure mathematics which neglects the distinction between experiments which can, and those which cannot, be carried out, or a mere collection of familiar formulæ with "proofs" which prove nothing but the author's incapacity for accurate thought. He actually tells us how important magnitudes are measured and what is implied by the fact of their measurement; he realises that to define a magnitude and to say how it is measured are one and the same thing. Yet he does not fall into the opposite vice and weary us with needless pedantry; many readers will probably appreciate his abandonment of the old inadequacies and inaccuracies only by finding that, for the first time, they truly understand.

However, it is needless to continue in this strain. The present reviewer is not acquainted with the first volume of M. Ollivier's work and must confess that he had never heard of the work until it came into his hands for review. Many others are probably in a similar state of ignorance. The best that he can wish

for the future of physics is that such a condition should become impossible, that "Ollivier" should become a household word and his treatise (if it is all equally good) be found in the library of every serious physicist.

Science Primers.

(1) *First Course in General Science.* By Prof. Frederic Delos Barber and others. Pp. vii+607. (New York: Henry Holt and Co.; London: G. Bell and Sons, Ltd., 1916.) Price 9s. net.

(2) *The Science of Everyday Life.* By E. F. Van Buskirk and E. L. Smith. Pp. xvi+416 (London: Constable and Co., Ltd., n d.) 7s.

(3) *A First Book of General Science: An Introduction to the Scientific Study of Animal and Plant Life.* By A. T. Simmons and A. J. V. Gale. (First Books of Science) Pp. viii+145. (London Macmillan and Co., Ltd., 1921.) 2s. 6d.

THESE three books offer a good contrast between British and American tendencies as regards general science in education. In the two countries, the movements in this direction have been going on independently. In both cases, they sprung from efforts made, in the 'nineties, in two or three schools, to take a bird's-eye rather than a toad's-eye view of science—to use the words of the Principal of one of the Illinois schools. In both cases, again, the growth of the movement began to be rapid about ten years ago.

With characteristic thoroughness, the Americans are fast reducing their methods to a system. In this country we are still in the muddle which seems to be our natural habit of growth Now that examining bodies are issuing schedules of work to be done in this connexion, teachers may be forced to set their houses in order. Then, perhaps, the hardly-won freedom from traditional restraint may again be lost. It is to be hoped that the outcome will be more satisfactory in the way of awakening general interest in things scientific than the work of the last century proved to be.

(1) But to return to the contrast: in America, the teaching of general science is itself being developed into a science, in Britain, it remains an art. If in one case it might be more scientific, in the other it might well be more artistic. The book which Prof. Barber and his collaborators have written is among the best of its kind—and many good ones have been published across the water. It may even be objected that it is *too* complete. In a single column of the index, the following words occur: machines, malaria, maltose, meat, metabolism, monsoons, motors, mucor, mumps. Experience shows that anything like a proper assimilation of such mixed dishes occupies three or four years. Are the pupils to have the same text-book during all that time? Will not they tire of the style, the print, the binding? There is a certain value in change, if only for the incentive to make a new and better start. In such things, perhaps, the art of teaching lies.

(2) "The Science of Everyday Life" depressed us. It seemed such a good book spoiled—spoiled by the very riot of the science of teaching. Here we have done with chapters: the book is divided, instead, into two parts, five units, and eighteen projects. Every one of the latter is subdivided monotonously into introduction, problems, topics, and individual projects. A project, by the way, has been defined as a whole-hearted, purposeful activity proceeding in a social environment. Pupils may be expected to ask questions about their activities; but lest they should omit to do so, the authors give lists of questions which they ought to ask. When they have completed a project, the whole-hearted, purposeful, and active seekers after knowledge must feel that there is nothing more that they ought to know, can know, or want to know about it. Frankly, despite the authors' introduction, we can scarcely think of a surer way of killing initiative. Yet the subject-matter of the book is good, and teachers who are rather short of ideas might do well to study it. We ourselves found the diagram showing the various cuts in a side of beef instructive!

(3) "General Science," by Simmons and Gale, provides a refreshing contrast. Here the authors set out with a single aim: to make their young readers acquainted with the manner in which plants and animals live, and to describe some of the physical and chemical processes which are involved. A small book, the general purpose can be grasped by boys and girls; and they may hope to master the contents within a reasonable time. It is written as a man might write for men—children hate to feel that they are being written down to. The science of teaching does not obtrude itself upon the pages; which is not the same as to say that it is absent. That is where the art of teaching plays its part. The authors have compiled a book which is both sound and eminently readable. It is sure to find a wide acceptance.

C. I. BRYANT.

Atmospheric Electricity.

Électricité atmosphérique. Par B. Chauveau. Premier Fascicule: Introduction historique. Pp. xi + 90. (Paris: G. Doin, 1922.) 10 francs.

M. CHAUVEAU has set out to write a work on atmospheric electricity—a very laudable undertaking, for, as he says in his preface, there is no

such work in the French or English languages, while there are only two in German. He proposes a work in three parts: (i.) historical introduction, (ii.) the electrical field of the atmosphere, and (iii.) ions, ionisation, and radio-activity. Part i. has now appeared, and if it may be taken as a fair sample of the whole, we may expect a very welcome addition to the literature of the subject.

M. Chauveau commences his history with the celebrated letter from Franklin to Collinson (dated 1750) in which the great American philosopher suggests a method for testing the hypothesis, then fifteen years old, that thunder and lightning are electrical phenomena. From this commencement the following stand out as the milestones along the path of progress:

(1) The proof that thunder and lightning are electrical phenomena: Dalibard, May 1752; Franklin, June 1752.

(2) The discovery of the electrification of the atmosphere with clear skies: Lemonnier, Sept.-Oct. 1752.

(3) The discovery of the daily variation: Beccaria, 1753–1775.

(4) The discovery of the annual variation: De Saussure, 1785.

(5) W. Thomson's (Lord Kelvin) improvements in instruments and methods, and the introduction of the idea of electrical potential gradient: 1856–1874.

(6) The discovery of the conductivity of air: Linss, 1887; Elster and Geitel and C. T. R. Wilson, 1899.

(7) The discovery of "atmospheric radio-activity": Elster and Geitel, 1902.

(8) The discovery of a very penetrating radiation in the upper atmosphere: Hess and Kolhorster, 1911–1914.

In telling the story of the progress from milestone to milestone, M. Chauveau has related the history of the development of instruments and methods and described the many attempts to find physical explanations of the phenomena observed. At first the observations were made with insulated conductors, generally pointed, from which sparks were drawn, but Lemonnier tested the electrical state of his "collector" by noting whether it attracted powder, and by this relatively delicate method he first detected "fine weather electricity." Later rough electroscopes, fitted with pith balls or gold leaves, made quantitative measurements possible, and so led to the determination of the diurnal variation by Beccaria. With electroscopes it was possible to detect a change in the electrical state of an insulated conductor as it was raised and lowered in the atmosphere (induction effect), and De Saussure used this method with remarkable results in 1785. It was with the discovery of "the power of the flame" to charge a conductor exposed to the atmosphere, which Volta made about 1780, that trustworthy methods became possible, but this discovery remained practically unused, and it was not until W. Thomson took up the study of atmospheric electricity some seventy years later that measurements were put on a sound physical basis.

Hypotheses and theories to explain the observations are innumerable: Volta's theory of the separation of electricity on evaporation; Peltier's theory of a permanent negative charge on the earth's surface, partially dissipated into the atmosphere by evaporating water and returned on condensation; Sohncke's theory of friction between water and ice, and Brillouin's theory of the electrical separation caused by ultra-violet light falling on the ice crystals of cirrus clouds; these are the most important. But every theory to explain the maintenance of the earth's electrical field has failed, and we appear to-day to be further from an explanation of this fundamental phenomena than we have been at any previous time. Even now we do not know whether the earth with its atmosphere is electrically neutral or whether there is a residual charge, and at the present moment there is not a single theory seriously maintained to explain the constant interchange of electricity between the earth's surface and the lower atmosphere.

Forest Policy and Management.

(1) *Schlich's Manual of Forestry.* Vol. 1: *Forest Policy in the British Empire.* By Sir William Schlich. Fourth edition, revised and enlarged. Pp. xi+342. (London: Bradbury, Agnew and Co., Ltd., 1922.) 15s. net.

(2) *The Practice of Silviculture. With Particular Reference to its Application in the United States.* By Prof. R. C. Hawley. Pp. xi+352. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 22s. net.

(3) *Forest Mensuration.* By Prof. H. H. Chapman. Pp. xxii+553. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 30s. net.

(4) *A Short Manual of Forest Management.* By H. Jackson. Pp. x+70. (Cambridge: At the University Press, 1921.) 7s. net.

SIR W. SCHLICH has crowned a long life of devotion to the science and art of forestry by the publication of what is practically a new work, although it purports to be only a new edition of vol. 1 of his well-known Manual. (1) This volume is certainly the most valuable book on the economics and the history of British forestry that has yet appeared. It should

prove interesting to the statesman and the economist, as well as to the forester and the industrialist.

The first part treats of general principles. The utility of forests is considered directly, when concerned with actual products, such as timber, turpentine, tans, etc.; and indirectly, when it is a question of the influence of forests on climate, soil erosion, hygiene, æsthetics and ethics. The last three are more important than is generally believed; and Sir William pleads for the creation of woodlands near large towns, which will serve as recreation grounds for the people and at the same time produce timber finding a ready sale, so that the establishment of these city forests need not be a financial burthen. Glasgow, renowned for its municipal enterprise, is the first of our cities to acquire a forest area for the enjoyment of its inhabitants, the Ardgoil Estate.

After the subject of the State in relation to forests is discussed, the remainder of the book, some 300 pages, deals with the actual condition of forestry in the British Empire. The British Isles, India, Canada, Newfoundland, South Africa, New Zealand, and the Crown Colonies are treated separately. The natural history of the forests, their resources in timber, the modes of silviculture, government policy, education, etc., are all carefully described, sketch maps and statistical tables being added where required.

(2) Considering the vast amount of information on the practice of silviculture which is scattered in British and American forestry journals and official bulletins, it is remarkable how few formal text-books on the subject have been published in English. The present work by a Yale professor is therefore very welcome. It deals primarily with conditions in the United States; but as the principles of silviculture are the same everywhere, the book can be used by British students with scarcely any change or comment. It is a compilation, remarkably up-to-date, and rendering matter available for study which otherwise could be found only by long search in German and French books. The author's presentation of facts is clear, and well illustrated by suitable diagrams.

There is, however, one serious defect, the omission of the subject of reproduction of the forest by artificial means, the reader being referred for information on this point to "Seeding and Planting," a companion book by Prof. Toumey, also of Yale University. Artificial planting of trees is much more common with us than natural regener[illegible]ion; and the necessity of using another book will [illegible]some to British students. Prof. Hawley's exposit[illegible] the methods of natural regeneration is excelle[illegible]t the best chapter in the book is one deal[illegible]inning," a difficult subject. Another subj[illegible]eated in a fresh and original manner, is the disposal of the "slash" or rubbish which is left on the ground after felling operations. This is important, as on the removal of the "slash" depends in great measure the freedom of the forest from injury by fire, insects, and fungi. General measures of protection against these three agents of destruction, as well as damage caused by grazing, are treated in four short chapters.

An excellent feature of the book is an appendix of more than forty pages on terminology, which is really an alphabetical list with definitions of the terms used in the science and art of forestry. This glossary, which was drawn up in 1917 by the Society of American Foresters, will serve to stimulate accuracy of statement by foresters. German and French equivalents are given.

(3) Prof. Chapman's "Forest Mensuration" is the third text-book on forest mensuration which has appeared in English, and it is well designed to become the standard authority on the subject in the United States. The system of measuring timber in North America is totally different from ours. There, the contents of trees and logs are expressed in terms of the probable out-turn in sawn boards, according to a certain log-rule; hence the phrase "board feet." In the British Isles timber is measured as a raw material in terms of the real cubic volume. The American system introduces extraordinary complication into forest mensuration, some thirty log-rules being now in use in different parts of the country, no two rules giving the same result in board feet. A considerable part of the book is taken up with these log-rules and the principles underlying their construction—all of which is useless to the forester in Europe or India.

Nevertheless, a large part of the volume is of interest, for once log-rules are disposed of, the author is on common ground with his European fellow foresters, and gives a good account of recent developments of forest mensuration by Swedish and German writers. The accurate measurement of masses of standing trees is difficult, but is obligatory for purpose of valuation, and is of great use as a means of determining from time to time the increment of a growing wood. Upon a knowledge of the latter depends the fixing of the proper time for felling. Part III. deals with the laws of growth of stands of trees, and is by far the most interesting subject discussed, as the principles involved are the same in all countries where scientific forestry is practised. The preparation of yield tables and their application to predicting future yields are treated fully. The book will be useful in the reference library, but cannot be recommended as a handbook for British students, on account of its preoccupation with American practice.

(4) Forest management is little understood in the

British Isles, where owners of woods usually confine their attention to the practical work of planting, thinning, and felling trees, without having clear ideas of the financial problems involved. The objects of management are classified as being either physical or economic. The former apply to protection forests, maintained on mountain slopes to prevent erosion and mitigate disastrous floods, to forests on catchment areas that afford water supplies to towns, and to private woodlands on estates which are treated as amenity grounds for ornament and sport. An economic object of management applies to any forest worked for timber and other saleable products. Forests of this kind are commercial undertakings, and the scheme of management adopted here should be such as to render the woodlands a financial success, yielding the maximum soil rental and giving the highest net return on the capital involved. The principles underlying forest management are clearly explained in Mr. Jackson's little book, which can be recommended as an introduction to this important subject.

Thoughts on Scientific Advance.

Problems of Modern Science. A Series of Lectures delivered at King's College (University of London). Edited by Prof. Arthur Dendy. Pp. 237. (London: G. G. Harrap and Co., Ltd., 1922.) *10s. 6d.* net.

THE object of this series of lectures is stated to have been to "place before the general public the present position of some of the main branches of science and to point out the direction in which progress is being made or may be hoped for in the near future." The book will also be found useful by scientific workers who desire to know something of the advances made in regions other than their own. The names of the lecturers are a sufficient guarantee of the value of the matter presented. It is unfortunate that no index is provided, and, for this reason, perhaps the most useful function of a review is to give some indication of the contents of the book. But it is to be understood that the topics mentioned by no means exhaust the list.

Prof. Nicholson's lecture on mathematics shows that much more research work is possible in that science, and it gives a useful account of the quantum theory. In Prof. Dale's astronomical lecture, we find a summary of the present position of the nebular hypothesis. It is interesting to find that certain kinds of nebulæ may reasonably be looked upon as bye-products of evolution. Prof. Richardson gives us a valuable general account of the latest views on the structure of atoms, and also further statements with regard to the quantum theory. Prof. Smiles refers especially to the chemistry of plants.

Prof. Dendy's lecture is an interesting discussion on the various component sciences making up that of general biology. A remark on page 131 with reference to the widespread influence of physiological considerations may be noted—"It is perhaps unfortunate that our interest in ourselves as human beings has resulted in the concentration of attention upon the functions of the human body, almost to the exclusion of the lower animals, so that the development of this branch of Biology has been a very lop-sided growth." It is to be hoped that recent developments, especially at the Plymouth Marine Biological Station, will remedy this state of affairs.

Prof. Ruggles Gates deals with various botanical problems, more especially with those of genetics and mutations. Prof. Halliburton is mainly concerned with pointing out the importance of free fundamental research in physiological science and gives various examples where important practical application at a later date was quite unforeseen. Prof. Barclay-Smith devotes his lecture to a useful account of the formation of bone, which presents phenomena of much greater general interest than some would be inclined to suppose.

The book may be thoroughly recommended, and the price is not excessive in comparison with many scientific works at the present day.
W. M. B.

Our Bookshelf.

The Newcomen Society for the Study of the History of Engineering and Technology. Transactions, Vol. 1, 1920–1921. Pp. 88+18 Plates. (London: The Newcomen Society, 1922.) 20s.

IN technology as well as in science the value of a knowledge of the history belonging to a given subject is gaining recognition. One result of the celebration at Birmingham of the centenary of James Watt in 1919 was the formation, by a few engineers interested in historical research, of the Newcomen Society, and the first volume of the society's Transactions has recently been issued. As indicated in its sub-title, the object of the society is to encourage the study of the history of engineering and technology, and it is, we believe, the first society formed for such a purpose. It takes its name from Thomas Newcomen (1663–1729), the Dartmouth blacksmith to whom we owe the atmospheric steam-engine. The honorary secretary and treasurer of the society is Mr. H. W. Dickinson, of the Science Museum, South Kensington.

Besides the papers read during the session 1920–21, the volume under notice contains the first presidential address, a list of members, the rules and constitution, and an account of the first summer meeting. Mr. Titley, in his address, after giving a brief sketch of the steps leading to the formation of the society, passes in review the subjects which come within its scope, points

to the various activities open to its members, and emphasises the use of history in everyday work.

The first paper given is entitled, "Introduction to the Literature of Historical Engineering to the year 1640," and to this is appended a valuable bibliography of books relating to early inventions. Then follow interesting papers on "The Rise and Fall of the Sussex Iron Industry," "The Mystery of Trevithick's London Locomotive," and "The Invention of Roller Drawing in Cotton-spinning," all of which are illustrated by plates. The Transactions, which are well printed, will appeal, we think, to the general reader as well as the expert.

Espace, Temps et Gravitation: la théorie de la relativité généralisée dans ses grandes lignes. Par Prof. A. S. Eddington. Ouvrage traduit de l'anglais. Par J. Rossignol. Pp. xii + 262 + iv + 149. (Paris: J. Hermann, 1921.) 28 francs net.

In the introduction which has been written for this translation by Prof. P. Langevin we read: "Dès que m'est parvenu ce Livre où M. Eddington réussit à exposer de manière à la fois si simple, si vivante et si personnelle la merveilleuse transformation que le génie d'Einstein a introduite dans les conceptions les plus fondamentales de la Physique, j'ai pensé qu'une traduction en devait être faite pour permettre au public français de partager la joie que sa lecture m'avait fait éprouver.

"Une démarche immédiate m'apprit que l'initiative avait été prise quelques jours plus tôt par M. Jean Becquerel et que le travail était commencé dans les conditions les plus favorables, puisque je n'aurais pu proposer un meilleur choix que celui de M. Rossignol pour le traducteur, et que M. Eddington voulait bien s'assurer lui-même que les nuances, souvent délicates, de sa pensée seraient fidèlement rendues."

The French edition of Prof. Eddington's well-known book has thus appeared under ideal conditions, and it would appear presumptuous were one to express an opinion as to the merits of the translation. This edition is of greater length than the original English edition (see Nature, vol. 106, p. 822, 1921), as it has been supplemented by a theoretical part in five sections as follows: I. Elementary Principles; II.—The Theory of Tensors; III.—The Law of Gravitation; IV.—The Mechanics of Relativity; V.—Electricity. These sections are valuable additions to the original, and awaken regret that they were not included in the English edition. The translation will doubtless receive a warm welcome from our French colleagues.

Monograph of the Lacertidæ. By Dr. G. A. Boulenger. Volume ii. Pp. viii + 451. (London: British Museum (Natural History), 1921.) 3*l*.

The "Monograph of the Lacertidæ," by Dr. G. A. Boulenger, the first volume of which was published in 1920, is now completed by the issue of the second and concluding volume. In collecting the materials for this work Dr. Boulenger has not been content to rely entirely on the resources of the British Museum, but has travelled widely and far over all Europe and examined the collections of all the principal Natural History Museums. He has made a special point of searching for and examining for himself the type specimens of as many species as possible. The result is a monograph based on the examination of an immense material including the greater part of the actual type specimens.

Two features of this catalogue deserve special mention. The present whereabouts of the type specimens, where known, are given, information of the greatest value to future workers, and a full list of the specimens in the collections of the British Museum gives at a glance the resources of that Institution and should be particularly useful to specialists abroad.

The monograph is at once the most complete and the most authoritative on the Lacertidæ that has yet appeared, and will for a long time remain the standard work on the subject. It is, we believe, the last piece of work done by Dr. Boulenger in his official capacity at the British Museum. It is a fitting climax to the long series of catalogues and monographs on fishes, amphibia, and reptiles which have marked his great services to science at the British Museum.

British Museum (Natural History) Economic Series, No. 13. *Mites Injurious to Domestic Animals (with an Appendix on the Acarine Disease of Hive Bees).* By Stanley Hirst. Pp. 107. (London: British Museum (Natural History), 1922.) 3*s*.

This profusely illustrated little book on the mites infesting domestic animals is the thirteenth of the series of pamphlets on economic entomology issued by the British Museum (Natural History). Like its predecessors, it is designed on strictly practical lines, and the subject-matter cannot fail to appeal to a wide circle of interested readers, from the systematic entomologist and experimental pathologist to the breeder and fancier, be it of horses, cattle, pigs, dogs, rabbits, fowls, or bees. A little more than half of the book is devoted to the important family Sarcoptidæ and the various species of mange for which members of this family are responsible. Useful hints on the treatment and management of infected stock are supplied, and wherever these parasites have been known to transfer their attentions to human beings, the fact is mentioned. Parasites of this order may prove to play an important part in the transmission of infectious disease, not only from animal to animal but from animal to man; and to the medical or veterinary entomologist searching for a possible transmitting agent of some obscure animal plague, the accurate descriptions and illustrations supplied in this book will be very helpful. An interesting feature is the appendix devoted to the description of "Isle of Wight" disease (Acarine disease of bees) and its causation by the mite *Acarapis woodi* which inhabits the tracheal tubes of infected bees.

The Changing Year. By Anthony Collett. Pp. viii + 310. (London: Hodder and Stoughton, Ltd., n.d.) 15*s*. net.

Mr. Collett has done well to collect his delightful Nature essays, originally contributed to the *Times*, and to publish them in this more permanent form. They are worthy of preservation, for Mr. Collett is a field naturalist of first rank. He has a keen and accurate eye for observation and an ear tuned to record the music of Nature which he hears around him, and he combines with these a gift of expressing what his

senses have appreciated in simple yet delightful language which cannot fail to awaken in his reader that intense enthusiasm and love for Nature which he himself undoubtedly feels.

In this book Mr. Collett guides us pleasantly through the year, pointing out the sign-posts which mark the progress of the weeks and months: the awakening of the spring, the arrival of the birds on spring migration, the intense bustle and activity of the early months of the year, the quieter and more matured beauty of summer, the renewed activity of autumn with its preparation for the winter, and the calm peace of the winter months with always the promise of spring and life.

The book is full of useful facts and details which only the true field naturalist can acquire and observe. We regret that there is no index by means of which ready reference to these first-hand observations can be made.

Radio Receiving for Beginners. By Rhey T. Snodgrass and Victor F. Camp. Pp. 99. (London: Macmillan and Co., Ltd., 1922.) 3*s*. 6*d*. net.

THIS is a work professedly intended for those with very limited knowledge of wireless matters, but the author, in his endeavour to avoid technicalities in the introductory portion, has rather missed the opportunity of presenting the elements of the subject in a sufficiently tangible form for the reader, if really unacquainted with the principles of wireless working, to pick up readily the full meaning of the excellent chapters which follow. In these, we are conducted progressively through crystal reception, plain valve reception, regenerative working, and single and double valve amplification. A good typical arrangement of connexions is given in each case, but it is understood that many variations can prove equally satisfactory. All this part of the book is thoroughly practical, and its utility is not greatly interfered with by the fact that it refers to American conditions alone. The general hints and the chapter on aerial construction are full of useful points, and explanatory notes on some of the individual pieces of apparatus which make up the complete equipment are contained at the end. The author makes it amply clear that wireless reception requires care, skill, and practice to get really good results, and is a good deal more than buying a complete outfit and "listening in" with a telephone.

Applied Calculus: An Introductory Text-book. By F. F. P. Bisacre. Pp. xvi+446. (London: Blackie and Son, Ltd., 1921.) 10*s* 6*d*. net.

THE adjective "applied" is used by Mr. Bisacre to imply "the treatment of practical problems being preceded by a fairly full discussion of the necessary theory." We thus get a competent elementary account of the differential and the integral calculus, followed by applications to curves, maxima and minima, electricity and magnetism, chemical dynamics and thermodynamics. The chapter on electricity and magnetism is too short, while that on thermodynamics is quite long. An attempt is made to clear up the mystery of limits, but the success would be more certain if the example used for the purpose were not the rather trivial one of finding the limiting value of x^2 when x becomes equal to 10. It is doubtful whether "epsilonology" is at all in place in such a book, and the practical student will scarcely be impressed with its value in view of the author's treatment. The tables should have been more extensive; as they stand their usefulness is very limited.

Interesting features of the book are photographs and biographies of pioneers in the calculus and its applications. The mottoes at the heads of the chapters are often cleverly chosen, like "A snapper-up of unconsidered trifles" for the chapter on integration.

S. B.

The Care of the Adolescent Girl: A Book for Teachers, Parents, and Guardians. By Dr. Phyllis Blanchard. Pp. xxi+201. (London: Kegan Paul and Co., Ltd., 1921.) 7*s*. 6*d*. net.

IN her foreword to this book, Dr. Phyllis Blanchard explains that its object is to help teachers, parents, and guardians to provide adolescents with definite information concerning their own nature and to point the way to a proper utilisation of their energies.

After introducing the views of various authorities, Dr. Blanchard considers the instincts of the adolescent girl and the resulting conflict and repressions, and later, the pathological results of these repressions. The most important chapter is that devoted to the sublimation of the sex factor into other activities.

It appears that the author considers the adolescent conflict as entirely sexual in nature, but its solution, which may be described as an adjustment to the perpetual mate, is not the only one in which the guardian and teacher must assist. The adjustment to society, the failure in which gives us the recluse, the crank, and the social rebel, is practically ignored. An adjustment to the conception of the infinite, failure in which leads to the conflict found in nearly all agnostics and materialists, is only dealt with as a method of sublimation of the sex factor; from this point of view the author evolves a Christianity which, as Dr. Scharlieb states in her preface, is scarcely to be recognised as Christianity by those who have been brought up in any of the orthodox schools.

Hyperacoustics. By John L. Dunk. Division II. Successive Tonality. Pp. xi+160. (London: J. M. Dent and Sons, Ltd.; New York: E. P. Dutton and Co., 1921.) 5*s*. net.

THE first division of the author's work, "Simultaneous Tonality," was published in 1916 and was shortly afterwards reviewed in these columns (vol. 98, p. 306, December 21, 1916). At least one-third of the present volume is devoted to a "brief résumé" of the earlier book, and then the author passes on to the new aspect of his subject, "Successive Tonality." The method of treatment is similar to that adopted previously, and there is little to add to the notice of the first volume. The nomenclature is so complex that a glossary, occupying six pages of the text, is provided for the convenience of the reader. The author recognises the difficulty clearly: "The jargon of each particular science is a real obstacle, not only to the acquisition of knowledge, but to the sympathetic understanding by workers in parallel fields, who, occupied with their own formulæ, tend to be repelled

when confronted with the hieroglyphics of a sister science." The present reviewer is unable to agree that the "jargon" here employed is likely to promote clear thinking, and does not believe that it will ever form the basis of a common language among all who are interested in the subject.

Handbook for Field Geologists. By Dr. C. W. Hayes. Third edition, revised and enlarged by Sidney Paige. Pp. xi+166. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd, 1921.) 13s. 6d. net.

DR. HAYES's manual, well bound, with rounded corners and gilt edges, is clearly intended for the pocket or the haversack. It is based on the methods adopted by the United States Geological Survey, and covers a certain amount of simple topographic surveying for ascertaining correct positions. The diagrams to illustrate forms of outcrop are small, as is necessitated by the size of the page, and we may prefer the bolder treatment given to this subject in Dr. Elles's recently published "Study of Geological Maps." Some matters, such as the description of common minerals in Appendix I., with its old-fashioned chemical formulæ, might have been left to the text-books with which the surveyor must become acquainted before he goes into the field. The directions as to the collection of the remains of fossil vertebrates and the investigation of placer deposits will rouse feelings of envy among those whose work is confined to the British Isles. But is the work of a geologist ever so confined? For those who are true geologists because they travel, Mr Paige has provided a compact and handy guide. It points out, at any rate, on what details attention should be fixed G. A. J. C.

The Psychology of Medicine. By Dr. T. W. Mitchell. Pp. viii+187 (London: Methuen and Co., Ltd., 1921.) 6s. net.

THIS book is intended primarily for those who, without being students of medicine or psychology, wish to keep themselves abreast of modern thought in these subjects. The earlier chapters are devoted to a discussion of the various psychological theories, commencing with Janet's theory of dissociation and its connexion with hysteria and the hypnotic state, and then passing on to Freud's theory of repression. The rest of the book deals with the conception of the unconscious, with psycho-analysis, and with the classification, treatment, and prevention of neuroses. Psycho-analysis is described from three aspects, namely, as a method of investigation, as a doctrine of the content and process of the mind, and as a therapeutic method.

The clearness and impartiality with which Dr. Mitchell has considered conflicting views will be appreciated by the reader who requires only a general outline of modern psychology. A few notes are appended for guidance in selecting literature for further study of the subject.

Graphical Analysis: A Text-book on Graphic Statics. By W. S. Wolfe. Pp. xiv+374. (New York and London: McGraw-Hill Book Co., Inc., 1921.) 20s. net.

MR. WOLFE offers us a detailed study of the graphical methods as used in statical problems, with applications to the investigation of various types of structures. He first sets out the ordinary theory of force and funicular polygons. The graphical processes for finding centres of gravity, moments, and moments of inertia come next, and then bending moments and shearing stresses of beams. Frameworks follow, applied to all kinds of trusses, roofs, and arches. After a chapter on moving loads on bridges we get the study of masonry piers and masonry arches as well as of reinforced concrete. A chapter on design of beams and struts, and a chapter on miscellaneous problems, complete an exhaustive account of a most important subject. There are more than 700 diagrams, all very well drawn and reproduced. It is difficult to see what advantage there can be in using A-B to designate the line AB, or A-B-C to designate the angle ABC. In view of the alarming increase in the prices lately charged for scientific books, it is a pleasure to note the excellent get-up of Mr. Wolfe's book and its moderate price. S. B.

The Horniman Museum: A Handbook to the Collections illustrating a Survey of the Animal Kingdom. By H. N. Milligan. Second edition. Pp. 66. (London County Council, 1922.) 6d.

THIS is really an elementary account of the ar kingdom on the usual lines of descriptive zoology does not seem to refer definitely to any partic specimens placed on exhibition; but no doubt mos the forms mentioned are on view in the museum ca and serve instead of drawings. The statements are generally accurate and as precise as brevity permits. The style is clear, but assumes some familiarity with words not in the vocabulary of the general visitor, such as "retractile," "aberrant," "everted." If the class Myriapoda is retained, this is merely an instance of the "conservative attitude found convenient in a handbook to be used by the general public." To say that *norvegicus* and *rattus* are "specific names" is but to share a common error, and if the phrase "the Theromorpha contains" is a grammatical howler, it is the only one of its kind in this book. Mr. Milligan has accomplished a difficult task with much success.

Radioactivity and Radioactive Substances. By Dr. J. Chadwick. (Pitman's Technical Primer Series.) Pp. xii+111. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2s. 6d. net.

SIR ERNEST RUTHERFORD's words of commendation in the Foreword to this little book are well deserved. "It is a clear and accurate account of radioactive phenomena written by one who has a first-hand knowledge of the facts." "To all those who are interested in the development of our knowledge of this fascinating subject I can strongly recommend this book as a simple, concise, and accurate statement of the main facts and theories." The diagrams are numerous, and, though on a small scale, are remarkably clear. Similar volumes on other branches of modern physics would be welcome.

The Rural Community. By Llewellyn MacGarr. Pp. xv+239. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1922.) 8s. net.

THIS book deals in a very elementary fashion with the social and economic factors affecting the agricultural worker, and its chief merit is its extreme simplicity.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Primitive Crust of the Earth.

PROF. COLE's letter in NATURE of July 8, p. 39, concerning the earliest known rocks—a group of sediments—and their relation to the ortho-gneisses, will, I think, call forth the sympathy of students of African geology. In 1904–1905 I came to the conclusion that the para-schists of Southern Nigeria were older than at least the majority of the ortho-gneisses, and searched—without success—for the real foundation-stones which received upon their surface these earliest sediments.

Later I have suggested that the Turoka Series of para-schists of Kenya Colony may prove the oldest rocks of that part of Africa and have thought that, were the main directions of foliation of the ortho-gneiss mapped throughout that continent, we should find, not directions produced by dynamic metamorphism, but directions indicating the upwelling of granitic bathyliths along zones of failure of the primitive crust, *i.e.* foliation swirls on a huge scale akin to those produced by the flood of the Laurentian magma around the disrupted blocks of Grenville sediments. It might be possible to tell what section of the eroded complex was being studied by observations on the frequency of the occurrence of syntectics, the degree of admixture, the proportion of reconstituted sediments to ortho-gneiss, or even by a passage from complete to less complete metamorphism in the invaded rocks.

The newly established surveys of Uganda, Tanganyika Territory and Nyasaland will, one hopes, throw a flood of light upon this fascinating problem of the constitution of the African Archæan.

JOHN PARKINSON.

Action of Cutting Tools.

MR. MALLOCK's theory of cutting tools (NATURE, August 26, p. 277) is extremely illuminating, but the term "Coefficient of Friction" in his final paragraph seems scarcely justified, as it would imply that the shearing force is always in the same direction and thus independent of the material being cut, of the depth of the cut, rate of feed and tool angles.

In practice even among skilled workers there is considerable variation in the tool angles used, and there is no decided preference by the workman for a tool ground on a fine-grained emery wheel as against one ground on a coarse grindstone, this on very heavy work where the friction might be important. Moreover, the general variation in practical tool angles seems more related to what may be termed the pliability of the material. Thus, for mild steel and wrought iron, angles of 50° to 55° are common, for cast steel and cast-iron 60° to 65° or 70° are the rule, whereas the brass-finisher's tools are almost flat topped with an angle of 80° to 85°. Copper and aluminium turnings bend very nicely, and thus the sharp tool angle required for them agrees with the pliability theory.

This idea of pliability is not antagonistic to Mr. Mallock's main argument but strongly in support of it, for when a metal yields pliable turnings, these turnings slide on the upper face of the tool a great deal more than when they break off short as in a friable material. Thus the curly turnings of a pliable material may exert more frictional force on the upper face of the tool, but not necessarily because the coefficient of friction is higher. Pliable turnings can slide and thus cause friction: brittle turnings break off with very little sliding. This may be seen very clearly in the rough turning of gun barrels. With certain tool angles and not too heavy a cut, the turnings curl off and are hot, whereas with a more obtuse tool and even a heavier cut the metal crumbles off and is probably not so hot. In the latter case the surface turned has a corrugated periphery showing the periodic impulsive friction on the tool face. The friction theory thus leads to a plausible explanation of certain forms of "chatter." If the friction on the tool face fluctuates on account of either vibration or crumbling of the cutting, and if the system has a natural period in tune with what may be termed the crumbling wave-length, resonance occurs.

But for practical difficulties Mr. Mallock's theory might be of value to investigators of friction, for in no set of actual conditions is it likely that metal slides on metal with more intimate contact than near the point of a cutting tool. Even with cutting lubricants it is doubtful if any liquid reaches the point of the tool unless there is chattering.

In attempting any conception of coefficients of friction between the tool and the cuttings, a further difficulty arises which renders the comparison with clean dry surfaces almost impossible. In some circumstances the cutting of metals produces, in addition to the obvious turnings, a fine smooth powder. This is presumably produced by the abrasion of the cutting on the upper face of the tool, and it may be that this smooth powdered metal acts as a lubricant or ball-bearing for the escaping turning. If so, it would be another of Nature's modes of automatic alleviation—as tears allay the irritation of dust in the eyes, and as the skin is cooled by evaporating sweat.

Director of Research,
Research Association of British Motor and Allied Manufacturers.

15 Bolton Road, W.4, August 27.

The Smoke of Cities.

WITH reference to Prof. Cohen's article on smoke abatement in NATURE of August 26, p. 269, I should be much interested to know why Manchester smoke is qualitatively so much worse than London smoke. Comparing Guy's Hospital and Gower Street with the University of Manchester—the three places of which I have had sufficient experience to judge—I should judge that the quantity of dirt in one's laboratory is about the same, at any rate it is not obviously less in London and, so far as I remember, the published measures of atmospheric pollution confirm this impression. But the Manchester dirt is far more unpleasant and destructive to one's hands, papers, and apparatus. It seems to contain more very fine sticky particles, which get in everywhere and are difficult to clear off; the London dirt is more gritty and granular, makes things dirty enough but is comparatively easily removed. Any one who has spring-cleaned laboratory cupboards in the two places and essayed afterwards to clean themselves will have realised that the dirts are of quite diverse characters. From what Prof. Cohen says I should judge that London smoke is relatively less domestic in origin than the Manchester product, but it seems difficult to reconcile this with what one

knows of the two places Does the sort of coal make a difference, or the length of time it is kept before consumption? Or is much of the London dirt dust from other sources than coal fires, dispersed more widely than in the damper Manchester atmosphere?

A. E. BOYCOTT.

Medical School, University College Hospital, London, W.C, August 28.

PROF. BOYCOTT's statement is rather surprising; but I cannot think that the explanation is to be found in the larger amount of domestic smoke in Manchester. One would rather expect the reverse, and I can only suppose that the difference between Manchester and London dirt is due to the larger amount of dust not arising from smoke, as Prof Boycott suggests. Any difference in the quality of coal used in Manchester and London would scarcely have the effect he describes.

The point is an interesting one and I think could be settled by microscopic examination of specimens from the two towns. Soot is easily identified in this way.

J. B COHEN.

Thwaite Cottage, Coniston Lake, Lancashire, September 1, 1922.

Waterspouts.

WATERSPOUTS on Lake Victoria are very commonly seen from Entebbe, but at a long distance away, and though I have worked on the lake shores for nearly four years it was only two days ago that I first saw one near enough to be of real interest

I was in camp on the north end of Bugalla, the largest island of the Sese Archipelago. The camp lay about 300 yards from the shore of a small bay. At daybreak on June 30 there were very lowering black clouds and every indication of an immediate heavy storm. While looking out from the tent I suddenly saw that a waterspout was travelling obliquely towards us, and as it eventually came to within about 100 yards of the shore a very good view was obtained for about five minutes before it came to an end

The pedicle arose from a well-marked circular area on the water, which was otherwise only faintly rippled by the preliminary puff of wind before the approaching storm.

This circular area was evidently very violently disturbed as a cloud of vapour, greatly agitated, rose from it for a little distance

The pedicle was extremely narrow at its lower end, and not quite straight, being sinuous in outline. It broadened out gradually into a column which went up into the low cloud; the core of this column was much less dense than the periphery, and the violent upward spiral ascent of the water could be clearly seen.

So far I have described nothing unusual, but the following was quite new to me and seemed of great interest.

Surrounding the central core, but separated from it by a clear narrow space, was a sheath, the lower end of which faded away some distance above the water. The profile of this sheath was undulating, it being thicker in some places than others. A curious point is that this sheath *seemed* to pulsate rhythmically, but I could not say whether the appearance of pulsation might not have been an illusion caused by waves travelling up its outer surface.

This pulsation gave an uncanny suggestion of a live thing, which was aided by the violent spiral movement upwards in the central core, the clouds of vapour boiling round its base, and the movement of the whole across the water—indeed, we watched it spellbound until the pedicle dissolved away at the bottom, and the ascent of the part above brought the phenomenon to an end.

My wife watched with me, and is in entire agreement about the curious appearance of pulsation of the outer sheath.

Fig. 1 is a reproduction of a pencil drawing which

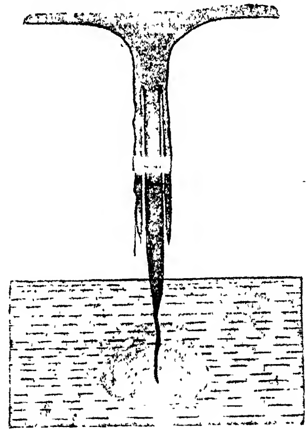

FIG. 1.

may give some idea of what we saw. I cannot estimate the height to which the column rose. Its cessation was followed by violent rain and thunder.

G. D. HALE CARPENTER,
Uganda Medical Service.

Entebbe, Uganda, July 1.

DR HALE CARPENTER's letter brings out one feature which has never, to my knowledge, been noted in a waterspout, namely, the sheath, separated from the main body of the whirl by a clear space. Wegener, in his book on "Wind- und Wasser-hosen in Europa," gives illustrations of a large number of waterspouts, but in no case is there mention of two trunks one within the other. The nearest approach to the phenomenon noted by Dr. Hale Carpenter is the not infrequent occurrence of waterspouts which show two clearly defined parts, an upper thick column with a lower whirl of much smaller thickness.

The accepted explanation of waterspouts is that they consist of whirls in rapid rotation with a discontinuity at the outer boundary. The rotation produces a rapid lowering of pressure within the whirl, and consequently a lowering of temperature, which may easily be sufficient to bring the air in the whirl down below its dew point. This is sufficient to explain the main features of the typical waterspout. The amount by which the temperature is lowered decreases outward from the "axis" of the whirl, while the difference between the air-temperature and dew point normally increases downward from the cloud level. The thickness of the visible column or zone of condensation therefore diminishes downward, giving the form of an inverted cone of irregular shape. Near the water the air is again near saturation, and the difference between air temperature and dew point is small, so that the base of the whirl is

widened. It frequently happens that the portion at middle heights is not visible, on account of the relative dryness of the air.

F. J. W. Whipple (*Meteorological Magazine*, February 1922), writing on cloud pendants, shows that within a whirl of 20 metres diameter, rotating once in a second, with a lowering of pressure of 30 mb. at the centre, the maximum wind speed would be 70 metres per second, or 160 miles per hour, in agreement with winds estimated in tornadoes A deficiency of 30 mb. pressure represents a suction sufficient to support 1 foot of water only. The solid appearance of a waterspout is therefore not to be ascribed to the lifting up into the air of a solid column of water, but is due partly to the condensation of water vapour within the whirl itself, and partly to water drops which are carried upward in spiral paths. This upward motion of water drops is a well-marked feature of most waterspouts.

The existence of an outer sheath, separated from the central core by a clear space, would appear to require a discontinuity of water content of the air, symmetrical about the axis of the whirl. It does not appear possible to explain it even as the effect of discontinuities of velocity within the whirl. No physical explanation of this clear space can be suggested.

It is usually suggested in text-books (for example, Humphreys's "Physics of the Air," p. 213) that waterspouts are formed at the boundaries of wind currents of different directions. But as such boundaries are of considerable extent, it is difficult to understand why single waterspouts ever come into existence. One would rather expect to find large families of waterspouts distributed over a considerable area. It is true that usually several are seen at the same time, but isolated cases are not infrequent.

The fact that Dr. Hale Carpenter, while standing within about one hundred yards of the waterspout he describes, apparently felt no wind from the whirl, testifies to the very limited diameter of the whirl in question

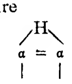
Periodic Structure of Atoms and Elements.

A. C. CREHORE, in his recent papers on "The Hydrogen Molecule" in the *Philosophical Magazine* (October 1921, May 1922, and June 1922), makes use of the specially constituted atoms of hydrogen and helium discussed by him, and of a hypothetical atom, the atomic weight of which is $2\frac{1}{3}$, to build up some of the other atoms. He uses H particles, hydrogen with charge $+e$; α-particles, helium with charge $+2e$, and particles of his hypothetical element, with positive charge $+e$. I think it is clear that he recognises the need for a helium particle with positive charge $+e$ in addition, if neutral atoms are to be built up in the way he indicates. In one of his models one of the particles marked 4 is also marked with a dot, and this evidently means that it has a charge $+e$ only. Calling these particles γ, glucinum or beryllium becomes α, γ, H and its structure appears to be $\gamma \overline{\underline{\quad}} \alpha \overline{\underline{\quad}} \mathrm{H}$, where the hyphens indicate electrons. Its isotope, of atomic weight 12, is $-\gamma-\mathrm{H}-\gamma-\mathrm{H}\ldots$, forming a simple ring of unit-charged particles. Nitrogen is 2α, γ, 2H, and may have the structure



Fluorine, instead of having the constitution assigned to it by Crehore, may be 2α, 2γ, 3H, and may have either of the two following structures:

$$=\alpha \begin{array}{c} -\gamma-\mathrm{H}-\mathrm{H}- \\ -\quad\gamma-\mathrm{H}\quad- \end{array} \alpha \;\vdots\;\vdots\;\vdots$$

the α's joining up to form a ring, or

$$\begin{array}{l} -\gamma-\mathrm{H}- \\ -\gamma-\mathrm{H}- \end{array} \begin{array}{c} \ulcorner\!-\mathrm{H}-\!\urcorner \\ \alpha \;-\; \alpha \end{array} \begin{array}{c} \ldots \\ \ldots \end{array}$$

the two γ's joining up to the α on the right to form a ring.

Starting from the element of lowest atomic weight in each of the groups of the periodic table, I have found it possible to build up all the other elements of these groups, with atoms of distinctly similar structure for each group, and marked differentiation between the different groups. This has already been carried out up to uranium for nearly all the groups, so that hypothetical models, of the correct atomic weight and atomic number, could now be constructed for the majority, and probably for all, of the known elements and their actual and probable isotopes. Uranium (U.I.) has been assigned the structure

$$=15\alpha \begin{array}{c} -7\gamma- \\ -7\gamma- \end{array} 15\alpha \begin{array}{c} -7\gamma-\mathrm{H}- \\ -7\gamma-\mathrm{H}- \end{array} \alpha =$$

forming a ring-shaped chain of thirty-one α-particles joined up by two equal chains of 7γ particles and two other equal chains of 7γ and one H particle. This type of structure may be assigned to elements of Group VI.

Transmission of Sound of Explosions.

READERS of NATURE may be interested to know that a Commission appointed a year ago for investigating the transmission of sound of explosions is arranging for an experiment on this subject to take place on a day to be notified as soon after September 23 as the weather will permit

On this occasion it is the War-Minister of the Netherlands who has been able to assist the Commission by notifying it of the intention to explode, on the day to be appointed, some 10,000 kilogrammes of perchlorate of ammonium at 19·30 (western European time), the main explosion will be preceded by a small explosion of a mass of 500 kilogrammes at 19·25.

I learn these particulars from Prof. Van Everdingen, director of the Meteorological Service of the Netherlands, who tells me that the countries surrounding the locus of explosion—Oldebroek, Lat 52° 29′ 56″ N., Long. 5° 59′ 40″ E —within 500 kilometres, are being invited to instruct their observers to watch for evidence of the explosion.

Human Geography: First Principles and some Applications.[1]

By MARION I. NEWBIGIN, D.Sc.

IT is a curious fact that, although geographers are agreed that man's intelligence and power of acquiring and transmitting knowledge so differentiate him from animals that it is necessary to distinguish between human geography and animal geography, yet, so far as I am aware, little detailed consideration has been given to the question as to the respects in which his response to environmental conditions differs from that of the animals. This is unfortunate, more especially since, thanks to the biologists, we have a fairly clear idea as to the mechanism of the response in the latter case

If, for example, we take two familiar animals, such as the rabbit and the common hare, we find that, though belonging to the same genus, and generally resembling each other in structure, they show certain minor differences in bodily form and habits fitting them for their respective environments The biologists are broadly agreed that these differences are an adaptive response to the different environments of the two animals. In explaining the origin of that adaptive response, most of them lay stress on the two factors of fixation to a particular environment and isolation—actual or physiological—within it, so that incipient variations are not swamped by intercrossing. Now when we turn to man, two facts are at once apparent. First, at the present time, he does not appear to respond to environmental influences by adaptive modifications of bodily form Secondly, there was certainly a time, before he had come fully to his heritage, when he did so respond. We know this because the anthropologists are agreed that while man once ran into a number of species and of genera—now all living human beings belong to the same species, and even the races show marked signs of being in process of becoming swamped by intercrossing In other words, there was a time when there was no human geography, when man reacted to the sum total of the conditions as an animal does; but that time appears largely to have passed.

But there is certainly still a human response to environmental conditions. What precise form does it take? To a certain minor extent, apparently as an inheritance from what I regard as essentially the prehuman period, there is a direct structural response But man's real response to the surface phenomena of the earth takes the form of a communal, not an individual response. It is the aptitudes which the members of a community display, the tools which they use, the kind of knowledge which they accumulate, their modes of organisation, their type of material wealth, their traditions and ideals, which show the environmental imprint most closely—far more closely than the colour of their skins or the shape of their heads.

But when and how did the change in the two modes of response come about? To answer this question let us recall what has been already said as to the importance of fixation and isolation in the case of animals. The surface of the earth is almost infinitely diverse, and what the biologists call natural barriers, the major barriers like deserts, seas, and mountain chains, or the minor ones produced by the transition from one type of plant formation to another—*e.g.* from the forested river valley to the grass-covered upland—separate different types of environment, and form obstacles to the distribution of most land animals. There must have been a time when groups of men, no less than the pigs in the forest or the asses on the steppe, were firmly gripped by the physical conditions, were isolated from other groups, and forced to become fitted by structure and habit for a particular set of conditions, or to die out. But with his growing intelligence man escaped from this iron grip, learnt to make virtually every part of the surface yield enough for survival, and proved capable of overcoming every kind of natural barrier When this occurred the old mechanism of adaptation largely though not completely—ceased to work. Evolution then might have ceased also, man might have become specially fitted to no environment because fitted for all, if the factors of fixation and isolation had not, in quite a different fashion, obtained a new hold.

Man ceased, save in relatively few parts of the earth's surface, to be a continuous wanderer He settled down afresh on particular parts of it, and there learnt to use his increasingly complex brain not only in utilising to their full the natural resources, but also in modifying the local conditions so that new resources became available. In other words, I wish to suggest that the cultivation of the soil was the great agent in ensuring the new type of fixation to a particular area which once again made evolution possible But evolution now took the form of increasing development of communal life, or, in other words, the growth of what we call civilisation is the precise equivalent of specific differences in plant or animal.

Further, just as, in the case of the animal, isolation is necessary before an incipient species can become fixed, so in the case of human communities a measure of protection from the inhabitants of neighbouring areas—a measure, that is, of isolation—is essential before civilisation can develop

Again, in the case alike of plants and animals we know that where the local conditions are such that the incipient species is limited to a very narrow area, highly specialised forms of adaptation may occur, as they do, for example, on many islands, or in isolated mountain chains; but that specialised type of development is associated with the loss of the capacity to vary, to acquire adaptations fitting the organism for a wider area. So in the case of human communities, where the isolation is too complete the power of adaptation tends to be lost, and such groups, though their civilisation may, along its own lines, be of a highly specialised type, are easily overwhelmed when contact with the outside world does occur, just as island animals tend to disappear before introduced forms.

With these general statements as starting-point, let us consider some facts in regard to the development of civilisation in Europe and the margins of the adjacent continents.

In this area history has seen three successive great

[1] From the Presidential Address delivered to Section E (Geography) of the British Association at Hull on Sept. 7

foci of civilisation, each based on well-marked and distinctive geographical conditions. The development of the three types has been successive and not simultaneous, and there has thus been a steady shift in time of the main focus, a shift westward and north-westward The three types of human societies alluded to are, of course (a) the river valley type as represented in Babylonia and early Egypt; (b) the Mediterranean type on parts of the seaboard of the Midland sea; (c) the forest type of Europe proper, itself becoming progressively more and more influenced by the greater ocean to the west, so that forest influences have steadily given way to maritime ones.

It is not necessary to consider the geography of these areas in detail But, beginning with Babylonia and Egypt, I should like to put the causes which seem to me to have promoted fixation quite briefly Among them we must certainly include the primitive natural resources, scanty though these doubtless were. The birds of the valley marshes, the relatively small number of mammals, the fish of the rivers, must have supplied a certain amount of the animal food. The date palm, in the Tigris-Euphrates areas at least, would, even in its wild state, doubtless yield a fruit of some value in the very early days

But as an important factor in the development of cultivation, I would lay especial stress upon the presence of what the botanists call the "open" plant formation. Native trees, as we know, are very few, the date palm, one of the most characteristic, being strictly limited in distribution by its need for water at the roots For the greater part of the year the ground between the scattered trees is naturally either devoid of vegetation, or is represented only by a few desert plants. But after the periodic flooding by the rivers, an abundant growth of vegetation springs up The plants may be annuals, the seeds of which ripen as the ground dries, and lie dormant till moisture comes again, or they may be bulbous and tuberous forms, having but a short period of vegetative activity, but possessing underground stems capable of withstanding prolonged drought. The result is that man did not require to clear land for crops; Nature periodically cleared it for him He had but to make the fairly obvious deduction that water alone was necessary for the apparently barren soil to blossom like the rose, from all the choice of plants which the flooded ground offered, he had to pick out those of some use to him, and learn to suppress the rest As has often been pointed out, he had no need to trouble greatly about renewing the fertility of his lands, for the flood-water did this for him.

So soon as he had learnt the initial lessons of cultivation, he was tied to the area normally flooded at certain seasons, or to which he could lead the flood-water. He intercalated his crops along one of Nature's lines of weakness, in a transitional area which passed periodically from one climatic zone to another, being, according to the seasons, either a desert or fertile.

The bordering desert ensured isolation, and, continuing the island metaphor, we may say that it represented the sea Its effect was to throw the whole energy of the community towards the centre, for the periphery formed an area in which the characteristic mode of life could not be practised. Similarly, it gave protection, for it is unsuited to any save a highly specialised culture, which must have been of relatively late origin. So far as it formed the boundaries of the incipient state, therefore, the desert constituted a barrier preventing the ingress of potential foes In neither case, of course, was the desert rim complete, and the conditions upstream varied in the two areas, and were, as has often been pointed out, from the point of view of safety, on the whole less favourable in the case of Babylonia than in that of Egypt

As to the third point, it is, I think, easy to show that while the isolation of the areas was markedly conducive to the rise of civilisation and to its growth up to a certain point, in the long run it became a danger. First, the contrast between the belt which could be watered and that to which, with the means available, water could not be carried, was exceedingly sharp. There was little possibility of a gradual spread into areas becoming slowly but progressively different, where new aptitudes could be acquired, new experience gained, and new forms of wealth stored Specialisation was high within the favoured tract, but the limits set by Nature could not be passed

Again, as has often been noted, the conditions led necessarily to a centralised and imperialistic form of social organisation. If there was a sharp line of demarcation between the areas which could and could not be watered, there were great possibilities in the direction of extending by artificial means the belt over which the flood-water spread This involved the gradual growth of an elaborate irrigation system, and for the maintenance of this a centralised power was essential This brought with it, as a correlated advantage, the possibility of organised defence when developing neighbouring communities attempted to encroach. But if the attack was made with sufficiently powerful forces, the centralisation became a menace. An attacking foe able to destroy or damage seriously the irrigation system could cut off at its source the basis of prosperity, and render reconstruction on the old scale almost impossible. In other words, the community became adapted to artificial conditions created by itself; if and when those conditions were destroyed, the survival of the old culture became impossible

Turn next to the Mediterranean region, that is, to the area in which the typical Mediterranean climate prevails In so far as the native plants are concerned, this area shows certain broad general resemblances to the river-valleys, with some striking differences Thus the characteristic plant formation is alternately open and closed: closed during the cooler season of the year when the winter rains cause a brief but intense growth of annuals and bulbous or tuberous plants, open during the drought of summer when the trees and shrubs stand apart from each other with bare earth between. But the contrast is due, as indicated, to the rainfall conditions, not to flooding. There is thus no natural renewal of fertility, and plants which require much water can only thrive in the cooler season, so that growth is less intense than in either the Nile or the Euphrates-Tigris valley.

On the other hand, because of the climatic conditions, trees and shrubs, alike as regards individuals and species, are far more numerously represented in the Mediterranean region. Here, however, we come to a

very curious fact, which, though it is familiar enough, does not seem to have been considered in all its bearings. This is that, despite the (relative) wealth of native species of shrubs and trees, those which are cultivated seem to have been for the most part introduced. This is apparently true even of the supremely important olive. The tree occurs in the fossil state, and the olivaster of the maquis is believed by many to be truly wild, not feral. Yet it would appear almost certain that the *cultivated* olive was introduced, into Europe at least. The same thing is true of great numbers of other species, and of all the fruit-bearing trees now grown in the area there are few indeed which can be reasonably regarded as having originated there as cultivated forms. Now, the deduction that I would draw is that the Mediterranean area is one in which lessons first learnt elsewhere could be easily practised, but one rendered unsuited by the natural conditions for the taking of the first steps.

Man was doubtless first attracted to the area, as in the case of the river-valleys, by the natural resources, small though these must have been, even with the addition of the sea fisheries. He became fixed to it when he learnt that the hill spurs gave safe sites for settlements, while affording easy access to the slopes on which he could carry on his special form of intensive cultivation. That form, as already suggested, was a derived and not an original one. He replaced the native trees and shrubs by useful cultivated varieties or species, which had, certainly for the most part, originated elsewhere He intercalated short-lived annuals like corn crops and beans along the line of weakness indicated by the periodic opening and closing of the natural vegetation. But one of his great difficulties was always that the absence of much level land and the climatic conditions rendered the growth of such crops relatively difficult, much more difficult than in the river-valleys.

If we think of the early settlements as showing a general resemblance to the Berber villages of the Algerian Atlas to-day, we realise that they were more or less isolated from one another, so that the social polity was of a wholly different type from that existing either in Babylonia or in early Egypt. But, and this seems to me important, although the natural conditions—especially the fact that fertility was limited to certain areas—made a measure of isolation inevitable, yet the sea gave a possibility of free movement in all directions which was absent in the river-valleys. Thus oversea, if not overland, spreading could take place, and the changes in the geographical conditions as the sea is traversed westward are relatively small, not outside the limits of adaptation. Thus we have the spread of the higher forms of Mediterranean culture from the eastern end of the sea towards the west, with the founding of new settlements of generally similar type to the old. This possibility of free movement brought with it a wider range of adaptability, a constant willingness to profit by new experiences, which has proved of enormous value to the world at large.

But with all its advantages the Mediterranean area, as already stated, had the great disadvantage that bread-stuffs were difficult to produce in quantity. Two methods of getting over that difficulty could be and were practised. For example, the ancient Greeks, having, it would appear, learnt the lesson from the Phœnicians, dared, in course of time, to descend from their hill-spurs to the sea-coast, in order to supplement the scanty resources of their limited lands by sea-trading. After a long interval the medieval cities, especially of Italy, did the same thing on a greater scale and with the advantage of a wider market. Between the two periods Rome tried the other possible method, that of holding in subjection the areas, outside that of the characteristic climate, which were corn-producing. Her failure was, at least in part, due to geographical causes. The great advantage of the method of sea-trading was the increase in the power of adaptation which it brought, as a result of the continual peaceful contact with other lands and other peoples. The decay of the splendid medieval cities of Italy came when the Mediterranean ceased to be a great highway of commerce, and the vivifying breezes from the outside world which had swept through it took another course—once again, therefore, a civilisation based upon a delicate adjustment to a particular set of conditions fell when those conditions changed.

Let us turn next to the third great area where, comparatively late, a complex civilisation grew up, that of the forest belt of Central and Western Europe. Here the conditions appear relatively so unfavourable that man could scarcely have solved the problem of fixing himself permanently to particular areas, and adapting himself to them, were it not for the help of the experience gained elsewhere. The great agent in transmitting that experience was, of course, first the Roman Empire, and then the Church which was the direct heir of the empire.

The essential difficulty here was that the characteristic plant formation was the closed temperate forest. At first sight there appears to be within it no line of weakness along which cultivated plants can be intercalated, and the establishment of cultivation seems to depend upon the complete destruction of the natural vegetation, involving the slow and peculiarly laborious clearing of the forest. Had the temperate forest been in point of fact as continuous as we are apt to assume, the problem would have been so difficult that the hunter's life in the forest might have lasted much longer than it did. We know, of course, that there were always "islands" in the sea of green, and of these the most important, from the point of view of the development of cultivation, were the loess areas and the lower uplands, especially those over chalk. We have, therefore, as our starting-point in this case scattered settlements in the woods—not compact ones like those of the Mediterranean region. As to the next stage, the surrounding wood must be regarded from two points of view. Initially it formed a protection, the protective influence being strongest where the ground was ill-drained, owing to the dense thickets which covered the marshy ground. But, in contrast to both the types of region already considered, given the necessary tools for the clearing of the land, the particular type of cultivation could be extended almost indefinitely on the level, while leaving the woods on the rising ground to supply the necessary fuel, building material, and pannage for the swine. This was a great advantage, but it meant that the necessary protection was soon lost.

In North-Western Europe that protective influence was peculiarly necessary for one geographical reason, as it was on the eastern margin of the continent for another. It was necessary in the west especially, because the sea-coasts, owing to the local wealth of fish, early attracted population. But in many regions those coasts, exposed to the oceanic type of climate in its most pronounced form, were unsuited to cultivation. At the same time, on account of their sheltered inlets, parts of those coasts were well fitted to breed a seafaring folk. Unable, or able only to a very small degree, to supplement their natural resources by cultivation, having at the same time command of the sea, those seafarers tended constantly to raid the painfully cleared and cultivated lands of their more fortunately situated neighbours, who, time and again, found their encircling woods a protection. We must suppose, therefore, that the tendency to clear more and more land would be checked by this need for the shelter of the woods.

But it seems to me that we may regard the growth of feudalism, from one point of view, as an adaptive device by which the growing agricultural settlements obtained, at a price, the necessary protection. Feudalism, in the form, for example, in which it grew up in England before the coming of the Normans, was a means of ensuring the existence of a kind of organisation which permitted clearing of forest land to go on indefinitely, while diminishing the risk of perpetual raiding.

It was also, more especially in Eastern Europe, something more, for it tended to fix the cultivator to the land. The tendency to wander may be said to be almost universal in the case of forest-dwellers carrying on primitive agriculture. Its wide distribution is due to the great difficulty of maintaining there the fertility of the land, more especially when exhausting crops, like the different kinds of grain and flax, are grown.

Feudalism helped in the solution of this problem by checking the natural tendency of the cultivator to abandon exhausted lands and move on to new ones. But even apart from this particular device, the problem of maintaining fertility had to be tackled early in the West, because the relief made the forest far less continuous and uniform than in the East. It must have been obvious quite early that it was not illimitable. Conditions were different in the forest region of the East, where the vast, almost uniform plains, the absence of well-marked relief, and the breadth of the continent made the forest a more permanent and unmanageable element than in Western Europe. Here, therefore, we find in suggestive combination two peculiar features. The first is that the wandering instinct, the instinct that brought the Slavs from their eastward forest home far into Central and Southern Europe, still persists. It is said to be quite well marked in parts of Russia, despite all the artificial checks which existed under the old regime. Part of the difficulty of the Slav problem also lies in the fact that the effect of the habit of small groups of wandering constantly from one wooded tract to another is written large on the ethnological map.

The second peculiar feature is that feudalism, and feudalism in a very harsh form, survived here far longer than in Western Europe, and in fact, if not in law, had scarcely disappeared when the war broke out. I would suggest that the great significance of this form of social policy here was that it helped to counteract the effects of the natural conditions, that it was fundamentally an artificial device for rendering the population stationary, and enabling it to adapt itself to the local relief and associated phenomena.

Now, whatever its value in earlier days, the present chaos in Eastern Europe shows clearly enough that ultimately it checked social evolution, and became a serious menace. It was fundamentally the erection of an artificial barrier round the rural community, and led to the apparent loss of the power of slow adaptation to changing conditions, alike on the part of the overlords and of the freed serfs.

But in the eastern chaos another factor has to be borne in mind. In the Old Russia, south of the forested area, and extending both into what is and was Rumania, lie the great treeless plains. Parts of these, as the nineteenth century showed, are extraordinarily fertile and well adapted for cereal production. But, from the point of view adopted here, they suffered from the enormous disadvantage that there is nothing in the natural conditions to fix their inhabitants to special areas, thus enabling them to acquire qualities fitting them for life there, nothing to give protection from constant inroads from Asia. Literally wastes for long centuries, these plains were for the most part ultimately incorporated in Imperial Russia, and deliberately colonised, often with colonists from a distance. The colonists were brought from areas of other characters, possessed traditions and aptitudes due to long experience of different geographical conditions, and were in the grip of a Government which had itself evolved under those conditions. There was thus no question of the possibility of the evolution of a type of culture bearing the imprint of the local conditions.

In consequence Russia to-day—as well as to some extent Rumania—is faced with a double problem. In both regions parts of the constituent lands are fitted for the mixed cultivation of the forest belt, and in them the old social policy has shown itself unfitted for modern conditions, and a new one has yet to be evolved. Other parts, again, have never developed even an imperfect social policy which was a response to their own local environment. Their apparent prosperity, till the outbreak of the war, was due to the fact that they were, economically though not politically, of the nature of colonies in relation to the industrialised West; they were, fundamentally speaking, the equivalents of Imperial Rome's corn-producing lands in North Africa and the Danubian plains. The chaos in Eastern Europe is thus having a reflex disturbing effect upon the West. The West has lost an important market, but that is perhaps in itself less important than the fact that over a large tract of European land man and his environment have been thrown out of gear, a catastrophic condition which inevitably disturbs equilibrium elsewhere. Just as in the later days of the Roman Empire disturbances in the marginal corn-producing lands shook and ultimately overthrew the centre, so are the centres of Western European civilisation to-day trembling under the impact of shocks

emanating from the East. We can well understand, therefore, how it is that there are those who believe that the focus of civilisation is destined to undergo another shift, and that the day of the predominance of North-Western Europe is drawing to a close.

The subject is not one which can be discussed here. But if I may sum up briefly the points I have been trying to make, I would say that the human geographer should have before him a twofold purpose. First, he should strive to show that the deductions which the biologists have slowly and painfully laid down in the course of the last sixty years apply, though with an essential difference—which requires careful definition—to the life of man. Secondly, he should use his precise knowledge of the surface of the earth to work out detailed applications of those deductions. In other words, human geography is the biology of man, and, on account of man's vast power of modifying his environment, necessitates a fuller knowledge of that environment than can be required of the biologist in the narrower sense. Investigations along these lines would, I think, promote greatly the interests of geography as a whole, both by making clear to the general public its value and in justifying that intensive study of the surface relief and the associated phenomena which must always remain its basis.

Educational and School Science.[1]

By Sir Richard Gregory

THE Educational Science Section of the British Association, which attains its majority this year, was established to consolidate the claims staked out by workers in different educational provinces, and promote common interest in their development as a whole. As Prof. H. E. Armstrong explained at the opening meeting, it was proposed to devote attention to education in all its branches with the object of introducing scientific conceptions into every sphere of educational activity; that is, conceptions which imply such exact and profitable treatment of a subject as should come from full knowledge. Educational science signifies, however, much more than methods of teaching or the theory of the curriculum. It involves conditions of physical, mental, and moral health, with their manifold types and variations, and the determination of the most appropriate, and therefore most effective, factors of growth at every stage of development. In its present stage educational science must be largely empirical, but in this respect it does not differ from meteorology, for example, and the laws which govern the perpetually varying contents and conditions of a child's mind are not much less precisely known or applied than those by which atmospheric changes are determined.

Education may, therefore, be defined as the deliberate adjustment of a growing human being to its environment; and the scope and character of the subjects of instruction should be determined by this biological principle. What is best for one race or epoch need not be most appropriate for another, but always the aim should be to give the pupil as many points of contact with the world around him as may be profitably developed during his school career. This does not mean, of course, that his vision is to be confined to contemporary necessities or his thoughts to provincial or even national fields. The resources available for his instruction and guidance comprise the wisdom and experience of the past as well as the power of the present, and in their extensive and varied character they now provide teachers with educational opportunities richer and fuller than those of any other period of the world's history. Literature and art form noble domains of the heritage into which the child of to-day is born, but they were mostly planted long ago, and their shapes have not been altered much in modern times. Science has, however, transformed the whole landscape entrusted to it, and the realm of its productivity is continually extending. It is a kingdom potent with possibilities for good or evil—an inheritance which cannot be renounced, and to let any of our children grow up unfamiliar with their entailed possession is to neglect an obvious duty.

The essential mission of school science is thus to prepare pupils for civilised citizenship by revealing to them something of the beauty and the power of the world in which they live, as well as introducing them to the methods by which the boundaries of natural knowledge have been extended and Nature herself is being made subservient to her insurgent son. We live in a different world to-day from that of medieval times, when the *trivium* of grammar, logic, and rhetoric, with the *quadrivium* of arithmetic, geometry, music and astronomy, comprised the subjects of a complete education in the sciences as well as in letters—different indeed from what it was only a century ago. The influence of science is now all-pervading, and is manifest in all aspects of human activity, intellectual and material. Acquaintance with scientific ideas and methods and applications is forced upon every one by existing circumstances of civilised life with its facilities for rapid transport by air, land, or sea, ready communication by telephone or telegraph, and other means by which space and time have been brought under control and man has assumed the mastership of his physical and social destiny. Science permeates the atmosphere in which we live, and those who cannot breathe it are not in biological adjustment with their environment—are not adapted to survive in the modern struggle for existence.

School instruction in science is not, therefore, intended to prepare for vocations, but to equip pupils for life as it is and as it soon may be. It is as essential for intelligent general reading as it is for everyday practical needs; no education can be complete or liberal without some knowledge of its aims, methods, and results, and no pupil in primary or secondary schools should be deprived of the stimulating lessons it affords. In such schools, however, the science to be taught should be science for all, and not for embryonic engineers, chemists, or even biologists; it should be science as part of a general education—unspecialised,

[1] From the presidential address delivered to Section L (Educational Science) of the British Association at Hull on Sept. 7.

therefore, and without reference to prospective occupation or profession, or direct connexion with possible university courses to follow. Less than 3 per cent. of the pupils from our State-aided secondary schools proceed to universities, yet most of the science courses in these schools are based upon syllabuses of the type of university entrance examinations—syllabuses of sections of physics or chemistry, botany, zoology, and so forth—suitable enough as preliminary studies of a professional type to be extended later, but in no sense representing in scope or substance what should be placed before young and receptive minds as the scientific portion of their general education. Such teaching excuses the attitude of many modern Gallios among schoolboys caring "for none of those things." The needs of the many are sacrificed to the interests of the few, with the result that much of the instruction is inept and futile whether judged by standards of enlightenment or of stimulus. Exceptional pupils may profit by it, but to others, and particularly to teachers of literary subjects in the school curriculum, it often appears trivial or sordidly practical, and is usually spiritless—a means by which man may gain the whole world, but will lose his soul in the process.

This impression is not altogether unjust, and the teaching of recent years has tended to accentuate it. The extent of school science is determined by what can be covered by personal observation and experiment—a principle sound enough in itself for training in scientific method, but altogether unsuitable to define the boundaries of science in general education. Yet it is so used. Every science examination qualifying for the First School Certificate, which now represents subjects normally studied up to about sixteen years of age, is mainly a test of practical acquaintance with facts and principles encountered in particular limited fields, but not a single one affords recognition of a broad and ample course of instruction in science such as is required in addition to laboratory work. I have not the slightest intention or desire to suggest that practical work can be dispensed with in the teaching of any scientific subject, but I do urge that it becomes a fetish when it controls the range of view of the realm of natural knowledge capable of being opened for the best educational ends during school life.

It is now generally recognised by educationists that up to the age of about sixteen years there should be no specialisation in school studies. The First School Examination was organised with this end in view, and seven examining bodies have been approved by the Board of Education to test the results of instruction given in (1) English subjects, (2) languages, (3) mathematics and science, which constitute the three main groups in which candidates are expected to show a reasonable amount of attainment. The number of candidates who presented themselves at examinations of the standard of First School Certificates last year was about 42,000; and of this number, 12,500 took papers in sections of physics, 13,000 in chemistry, 11,400 in botany, 5000 physics and chemistry combined under experimental science, 113 natural history of animals, 31 geology, and 3 zoology.

These numbers may be taken as a fair representation of the science subjects studied in most of our secondary schools, and they suggest that general scientific teaching is almost non-existent. Botany is a common subject in girls' schools, but the instruction in science for boys is limited to parts of physics and chemistry. The former subject is usually divided into mechanics and hydrostatics; heat; sound and light; and electricity and magnetism; and candidates are expected to reach a reasonable standard in two of these sections. They may, therefore, and often do, leave school when their only introduction to science is that represented by the study of mechanics and heat, and without the slightest knowledge of even such a common instrument as an electric bell, while the ever-changing earth around them, and the place of man in it, remain as pages of an unopened book. They ask for bread, and are given a stone. General science covering a wide field is practically unknown as a school subject, and even general physics rarely finds a place in the curriculum because questions set in examinations are, to quote from the Cambridge Locals Regulations, "principally such as will test the candidate's knowledge of the subject as gained from a course of experimental instruction."

One or two examining bodies have introduced general science syllabuses covering the rudiments of physics and chemistry as well as of plant and animal life, but even in these cases most of the subjects must be studied experimentally, and no place is found for any other means of acquiring knowledge. The result is that few schools find it worth while from the point of view of examination successes to attempt to cover such schemes of work. Moreover, no clear principle can be discerned by which the syllabuses are constructed. General science should be more than an amorphous collection of topics from physics and chemistry, with a little natural history thrown in as a sop to biologists. It should provide for good reading as well as for educational observation and experiment; should be humanistic as well as scientific. The subject which above all others has this double aspect is geography; so truly, indeed, is this the case that in the First School Examinations it may be offered in either the English or the Science group. A school course which would cover all the science required for the study of geography conceived as a branch of knowledge concerned with the natural environment of man and the inter-relations between him and those circumstances would not only be educational in the broadest sense, but would also be the best groundwork for effective teaching of geography, history, and other humanistic studies. It would make science a natural part of a vertebrate educational course instead of specialised and exclusive as it tends to be at present.

It cannot be reasonably suggested that the order in which the usual sections of physics are prescribed has any relation to mental growth, or that the topics selected from them are such as appeal to early interests. Few pupils of their own volition wish to determine specific gravities, investigate the laws of motion, calculate specific and latent heats, and so on, at the stage of instruction in science at which these matters are usually studied, and from the point of view of educational value most of them would be more profitably employed in becoming acquainted with as wide a range as possible of common phenomena and everyday things—all considered as qualities to stimulate

attention instead of quantities to be measured with an accuracy for which the need cannot be seen and by methods which easily become wearisome. The "Investigators" appointed by the Board of Education in 1918 to report upon the papers set in examinations for the First School Certificate were right when they expressed their opinion "that the early teaching of physics has suffered from too great insistence on more or less exact quantitative work, to the neglect of qualitative or very roughly quantitative experiments illustrating fundamental notions." By the prevailing obsession in regard to quantitative work the pupil is made the slave of the machine, and appliances become encumbrances to the development of the human spirit.

When instruction in science was first introduced into schools its character was determined by insight and conviction rather than by mental needs or interests; so later, when practical work came to be regarded as an essential part of such instruction, its nature and scope represented what certain authorities believed pupils should do, instead of what they were capable of doing with intelligence and purpose. Practical chemistry became drill in the test-tubing operations of qualitative analysis, and the result was so unsatisfactory from the points of view of both science and education that when Prof. Armstrong put forward a scheme of instruction devised by him, in which intelligent experimentation took the place of routine exercises, acknowledgment of its superior educational value could not be withheld, and for thirty years its principles have influenced the greater part of the science teaching in our schools.

Prof. Armstrong's particular contribution to educational science consisted in the production of detailed schemes of work in which these principles were put into practice. Ideas are relatively cheap, and it needs a master mind to make a coherent story or useful structure from them. This was done in the courses in chemistry outlined in Reports presented to the British Association in 1889 and 1890, and the effect was a complete change in the methods of teaching that subject. "The great mistake," said Prof. Armstrong, "that has been made hitherto is that of attempting to teach the elements of this or that special branch of science; what we should seek to do is to impart the elements of scientific method and inculcate wisdom, so choosing the material studied as to develop an intelligent appreciation of what is going on in the world." One feature of heuristic instruction emphasised by its modern advocate, but often neglected, is that which it presents to the teaching of English. Accounts of experiments had to be written out in literary form describing the purpose of the inquiry and the bearing of the results upon the questions raised, and wide reading of original works was encouraged. A few years ago English composition was regarded as a thing apart from written work in science, but this should not be so, and most teachers would now agree with the view expressed by Sir J. J. Thomson's Committee on the Position of Natural Science in the Educational System of Great Britain that "all through the science course the greatest care should be taken to insist on the accurate use of the English language, and the longer the time given to science the greater becomes the responsibility of the teacher in this matter. . . . The conventional jargon of laboratories, which is far too common in much that is written on pure and applied science, is quite out of place in schools."

When heuristic methods are followed in the spirit in which they were conceived, namely, that of arousing interest in common occurrences, and leading pupils to follow clues as to their cause, as a detective unravels a mystery, there is no doubt as to their success. No one supposes that pupils must find out everything for themselves by practical inquiry, but they can be trained to bring intelligent thought upon simple facts and phenomena, and to devise experiments to test their own explanations of what they themselves have observed. It is impossible, however, to be true to heuristic methods in the teaching of science and at the same time pay addresses to a syllabus. A single question raised by a pupil may take a term or a year to arrive at a reasonable answer, and the time may be well spent in forming habits of independent thinking about evidence obtained at first-hand, but the work cannot also embrace a prescribed range of scientific topics. Yet under existing conditions, in which examinations are used to test attainments, this double duty has to be attempted by even the most enlightened and progressive teachers of school science. There can, indeed, be no profitable training in research methods in school laboratories under the shadow of examination syllabuses. Where there is freedom from such restraint, and individual pupils can be permitted to proceed at their own speeds in inquiries initiated on their own motives, success is assured, but in few schools are such conditions practicable; so that, in the main, strict adherence to the heuristic method is a policy of perfection which may be aimed at but is rarely reached.

A necessary condition of the research method of teaching science is that the pupils themselves must consider the problems presented to them as worth solving, and not merely laboratory exercises. Moreover, the inquiries undertaken must be such as can lead to clear conclusions when the experimental work is accurately performed. It may be doubted whether the rusting of iron or the study of germination of beans and the growth of seedlings fulfils the first of these conditions, and the common adoption of these subjects of inquiry is due to custom and convenience rather than to recognition of what most pupils consider to be worth their efforts. It needed a Priestley and a Lavoisier to proceed from the rusting of iron to the composition of air and water, and even such an acute investigator as Galileo, though well aware that air has weight, did not understand how this fact explained the working of the common suction pump.

The mission of school science should not, indeed, be only to provide training in scientific method—valuable as this is to every one. Such training does cultivate painstaking and observant habits, and encourages independent and intelligent reasoning, but it cannot be held in these days that any one subject may be used for the general nourishment of faculties which are thereby rendered more capable of assimilating other subjects. Modern psychology, as well as everyday experience, has disposed of this belief. If the doctrine of transfer of power were psychologically sound, then as good a case could be made out for the classical languages as for science, because they also may be taught so as to develop the power of solving problems

and of acquiring knowledge at the same time. When, therefore, advocates of particular courses of instruction state that they do not pretend to teach science, but are concerned solely with method, they show unwise indifference to what is known about educational values. Locke's disciplinary theory—that the process of learning trains faculties for use in any fields, and that the nature of the subject is of little consequence—can no longer be entertained. It has now to be acknowledged that information obtained in the years of school life is as important as the process of obtaining it; that, in other words, subject matter as well as the doctrine of formal discipline must be taken into consideration in designing courses of scientific instruction which will conform to the best educational principles.

So long ago as 1867 the distinction between subject and method was clearly stated by a Committee of the British Association, which included among its members Prof. Huxley, Prof. Tyndall, and Canon Wilson. It was pointed out that general literary acquaintance with scientific things in actual life, and knowledge relating to common facts and phenomena of Nature, were as desirable as the habits of mind aimed at in scientific training through "experimental physics, elementary chemistry, and botany." The subjects which the Committee recommended for scientific information, as distinguished from training, comprehended "a general description of the solar system; of the form and physical geography of the earth, and such natural phenomena as tides, currents, winds, and the causes that influence climate; of the broad facts of geology, of elementary natural history with especial reference to the useful plants and animals; and of the rudiments of physiology." If we add to this outline a few suitable topics illustrating applications of science to everyday life, we have a course of instruction much more suitable for all pupils as a part of their general education than what is now commonly followed in secondary schools. It will be a course which will excite wonder and stimulate the imagination, will promote active interest in the beauty and order of Nature, and the extension of the Kingdom of Man, and provide guidance in the laws of healthy life.

The purpose of this kind of instruction is, of course, altogether different from that of practical experiment in the laboratory. One of the functions is to provide pupils with a knowledge of the nature of everyday phenomena and applications of science, and of the meaning of scientific words in common use. Instead of aiming at creating appreciation of scientific method by an intensive study of a narrow field, a wide range of subjects should be presented in order to give extensive views which cannot possibly be obtained through experimental work alone. The object is indeed almost as much literary as scientific, and the early lessons necessary for its attainment ought to be within the capacity of every qualified teacher of English. Without acquaintance with the common vocabulary of natural science a large and increasing body of current literature is unintelligible, and there are classical scientific works which are just as worthy of study in both style and substance as many of the English texts prescribed for use in schools. We all now accept the view that science students should be taught to express themselves in good English, but little is heard of the equal necessity for students of the English language to possess even an elementary knowledge of the ideas and terminology of everyday science, which are vital elements in the modern world, and it is the business of literature to present and interpret them.

It may be urged that knowledge obtained through descriptive lessons has no scientific reality unless it is derived from first-hand experience, and this is no doubt right in one sense; yet it is well to remember that science, like art, is long, while school life is short, and that though practical familiarity with scientific things must be limited, much pleasure and profit can be derived from becoming acquainted with what others have seen or thought. It is true that we learn from personal experience, but a wise man learns also from the experience of others, and one purpose of a descriptive science course should be to cultivate this capacity of understanding what others have described. As in art, or in music, or in literature, the intention of school teaching should be mainly to promote appreciation of what is best in them rather than to train artists, musicians, or men of letters, so in science the most appropriate instruction for a class as an entity must be that which expands the vision and creates a spirit of reverence for Nature and the power of man, and not that which aims solely at training scientific investigators.

The Royal Botanic Gardens, Kew.

THE area occupied by the Royal Botanic Gardens of Kew, as we know them to-day, is mainly the result of the union of two demesnes, both of them famous in a horticultural sense long before they came to be associated in particular with the science of botany. These two demesnes were, first, the grounds originally attached to a house in the Old Deer Park of Richmond known as Ormonde Lodge, Richmond Lodge, and finally, when it came to be occupied by George II. (then Prince of Wales) about 1721, as Richmond Palace; secondly, the grounds belonging to Kew House or White House, a dwelling that stood near the present Kew Palace, and which, after being occupied by the families of Bennett, Capel, and Molyneux, came into the possession of Frederick, Prince of Wales, in 1730. On the death of George II. in 1760, both properties came under the ownership of his grandson, George III. At that time they were divided by an ancient bridle-path known as "Love Lane," which ran from Richmond Green to a horse-ferry over the Thames at Brentford. George III. obtained Parliamentary sanction to close Love Lane, with the obliteration of which, in 1802, Richmond Gardens and Kew Gardens became the larger Kew Gardens we know at the present time.

In the aero-photograph here reproduced we are looking almost due north, and most of the area shown belongs to the Kew Gardens of the eighteenth century. It is bounded on the east by the Kew Road, some of the villas of which are shown towards the top right-hand

corner of the picture It is on this area that all the plant-houses, museums, and other buildings are situated. Richmond Gardens were bounded on the west by the Thames, and part of their site is the thickly wooded area shown towards the top left-hand corner of the photograph.

Under Queen Caroline, consort of George II., Richmond Gardens became famous for the costly and elaborate operations she carried out there. She built Merlin's Cave, the Hermitage, and various temples and other structures, all of which disappeared soon after George III. came to the throne Even Richmond Lodge itself was razed to the ground in 1772.

The old Kew Gardens had a longer and more interesting history. John Evelyn made several references to them in his Diary In August 1678 he records that the gardens had the "choicest fruit of any in England," and under the date February 24, 1688, he wrote, "we went to Kew to visit Sir Henry Capel's whose orangery and myrtetum are most perfectly kept" From the accounts of Evelyn and others it appears certain that, even 250 years ago, Kew was one of the best gardens in England.

Sir Henry Capel died in 1696, and the property descended to his grand-niece, the wife of Samuel Molyneux Molyneux had a taste for astronomy and converted part of Kew House into an observatory. It was here that his friend Dr. Bradley, afterwards Astronomer Royal, made his two important discoveries, the aberration of light and the nutation of the earth's axis. Kew House was pulled down in 1802, but the site of the observatory and Bradley's discoveries is now marked by a sun-dial.

The foundation of the Botanic Garden at Kew has to be credited to Augusta, Princess of Wales and mother of George III. Under the superintendence of Lord Bute, about nine acres were laid out in 1760, the portion devoted to herbaceous plants, then called the Physic Garden, being arranged on the then newly devised Linnaean System. William Aiton, a pupil of Philip Miller of Chelsea and afterwards the author of the "Hortus Kewensis," was appointed head gardener, and Sir William Chambers, the architect of Somerset House, erected a number of temples and other buildings, of which several, including the Pagoda, are still conspicuous features of the place.

THE ROYAL BOTANIC GARDENS, KEW

A=PAGODA B=TEMPERATE HOUSE. C=REFRESHMENT PAVILION. D=NORTH GALLERY. E=FLAGSTAFF. F=PALM HOUSE. G=WATER-LILY HOUSE. H=No III. MUSEUM (ORANGERY). I=KEW PALACE. J=POND. K=CACTUS HOUSE.

Between 1760 and 1841 Kew had a period of brilliant success and one of decadence. Princess Augusta died in 1772 and George III. substituted Sir Joseph Banks in place of Lord Bute as unofficial director of the Botanic Garden. Banks was largely interested in the fortunes of the garden until his death in 1820, and his association with it no doubt was the chief agency that ultimately gave it the premier position among

botanic gardens of the time. Plant collectors were despatched to various countries, the first being Francis Masson, who went to South Africa in 1772.

After the death of George III. as well as that of Banks in 1820, the gardens gradually declined in efficiency and repute, until at the accession of Queen Victoria there was a serious danger of their disappearance altogether as a botanic establishment. However, a committee of inquiry, headed by John Lindley, reported strongly in favour of their continuance and further development, and in 1840 their control was vested in the Commissioners of Woods and Forests. In 1841, Sir William Hooker was appointed director, and thus was inaugurated the second great period in the history of Kew.

During the last eighty years the area devoted to botany and horticulture has increased from about 15 acres to 288 acres. Its work as the botanical centre of the British Empire and for the distribution of economic plants to all our colonies and possessions is well known. To the public generally it is, of course, best known as a popular resort. Nor must its place as a training school in horticulture be forgotten, especially for curators of Colonial and Indian Botanic Gardens and superintendents of public parks at home. No better testimony of its value to the Empire can be adduced than that of Joseph Chamberlain, then Colonial Secretary, in the House of Commons on August 2, 1898: "I do not think it is too much to say that at the present time there are several of our important colonies which owe whatever prosperity they possess to the knowledge and experience of, and the assistance given by, the authorities at Kew."

In pure botany its chief work has been the preparation and publication of Floras of British possessions—a botanical survey of the Empire. Bentham and Hooker prepared their "Genera Plantarum" at Kew, and the monumental "Index Kewensis" was compiled there. The Herbarium contains some 2,500,000 specimens and the library upwards of 24,000 volumes.

Turning to the more conspicuous objects in the accompanying illustration, the one that catches the eye first is the Pagoda (A). This was erected by Sir William Chambers in 1761–2; it has ten storeys and is 163 feet high. From its summit the Crystal Palace is usually visible and, with a favourable atmosphere, Windsor Castle. During the coal strike in the spring of last year all the more lofty buildings as far as St. Paul's could be seen.

The Temperate House (B) is a structure of three main compartments, the large central one, built in 1862, being devoted largely to the cultivation of Australian and New Zealand trees and shrubs, the smaller ones, built 1897–1899, to Himalayan and subtropical ones. The North Gallery (D) contains 848 paintings of flowers and tropical and subtropical vegetation by the late Marianne North; both the paintings and the buildings were presented by her to Kew in 1882. The Flagstaff (E), which appears merely as a dark streak in the illustration, was presented by British Columbia, and is 214 feet high, 2 feet 9 inches in diameter at the base, 1 foot in diameter at the summit; at the time of its erection in October 1919 it weighed 18 tons.

The Palm House (F), where tropical plants, such as palms, cycads, pandanads, bamboos, and bananas, are grown, is an iron structure built 1844–1848. It is 362 feet long and 66 feet high in the centre. The Orangery (H) is one of Chambers's buildings and was erected in 1761. The orange trees originally housed there were transferred to Kensington Palace in 1841, soon after Kew became public property. It is now known as Museum III. and contains exhibits of exotic timber and miscellaneous objects.

Kew Palace (I), once known as the Dutch House, is a red brick, Jacobean dwelling, built by Samuel Fortrey in 1631. By his grandson it was sold to Sir Richard Levett, who was Lord Mayor of London in 1700, and in 1781 it was purchased from the Levetts by George III., who used it as a dwelling for himself and his large family when the Court was at Kew. His sons, the Dukes of Clarence and of Kent, were married in one of the rooms, and his wife, Queen Charlotte, died there November 17, 1818. It is now open to the public who visit the Gardens, but is not attached in any scientific sense to the establishment, containing only mementoes of the Royal Family.

Obituary.

DR. R. H. CODRINGTON.

IN the fulness of years, at the age of ninety-two, Dr. R. H. Codrington, the apostle of Melanesia, has passed away. After a distinguished Oxford career he became Fellow of Wadham; soon after, he joined Bishop Patteson and afterwards lived with Bishop Selwyn at Norfolk Island. After thirty-two years' service in the Melanesian mission he returned to England and became vicar of Wadhurst and Prebendary of Chichester. A friend who knew him well describes him as "the soundest of scholars, kindliest of teachers, most practical of saints, most genial and tolerant of friends." He will be remembered as the first and greatest ethnologist and linguist who studied the people of Melanesia. His fame rests on two great books—"The Melanesian Languages," and "The Melanesians, their Anthropology and Folk-lore," published by the Oxford Press in 1855–1891. The former laid the foundation of the scientific knowledge of the speech of that region; the second is invaluable to the anthropologist as giving the first and fullest account of religious beliefs. Dr. Codrington was also the discoverer of the principle of Mana, which has played a leading part in the exploration of savage religion since he made it known to the world.

THE *Chemiker Zeitung* for September 5 announces the death on August 7 of Prof. Emilio Noelting, for many years Director of the Chemical School at Mulhausen. Prof. Noelting was an authority on dye-stuffs; he was born on June 8, 1851, at Porta Plata, San Domingo, and after study at Zurich he took up his position at Mulhausen in 1880. In the issue for September 9 of the same journal the death is announced of Prof. E. Bergmann director of the Chemisch-Technische Reichsanstalt, Berlin.

Current Topics and Events.

Stagnation of trade in the year 1921 is responsible for a situation in the American dyestuff industry resembling, in many respects, that which prevailed in this country Firms engaged in the manufacture of coal-tar derivatives numbered 201, of which 74 produced colouring-matters with an output of 39,000,000 lb, while the sales exceeded 47,000,000 lb. Thus the domestic consumption of that year was in part supplied from the large stocks carried over from the previous year's abnormally high production Nevertheless, it is satisfactory to note that progress was made in the direction of a wider range, many dyes of greater complexity and more specialised application being produced and marketed for the first time in the United States; although such materials do not make substantial additions to the bulk of production, they are essential factors in the development of a flourishing domestic industry Further encouragement follows from the circumstance that in the year 1914 the United States imported nearly 46,000,000 lb of dyes and produced only 6,000,000 lb, almost entirely from German intermediates There are still requirements which have to be met from foreign sources, however, 3,914,036 lb. being imported in 1921, principally from Germany (48 per cent) and Switzerland (41 per cent), while this quantity exceeds by 511,454 lb. the amount imported in 1920, the average price has fallen from 1·7 dollars for that year to 1 3 dollars for 1921. Simultaneously, the price of domestic dyes has fallen from an average of 1·08 dollars per lb in 1920 to 83 cents in 1921 From an American standpoint, the most disturbing feature of the year under review is the diminution of exports, the value of which has fallen from 29,833,591 dollars in 1920 to 6,270,139 dollars in 1921; the total exports thus fell below those of the year 1917, when the first considerable expansion of the domestic dye-manufacturing industry from pre-war dimensions was noted

Subject to the sanction of Parliament, the Ministry of Agriculture is putting forward a further scheme for the drainage of agricultural land as a measure towards the relief of unemployment, especially in rural districts. It is estimated that last winter not less than 340,000 acres were relieved of flooding or water-logging, but a far greater area is still in need of drainage. The scheme is designed for the improvement of arterial drains and watercourses, and grants cannot be made in aid of such work as tile-draining or the cleansing of field ditches The work must in all cases be completed by March 11, 1923, as no public money will be forthcoming after March 31 next All schemes from Drainage Authorities must be submitted to the Ministry before December 1, and from County Agricultural Committees before December 16 As the main object to be achieved is to get unemployed men rapidly to work, the Ministry does not intend to let any unnecessary formalities stand in the way of schemes that can be put into operation promptly

The Journal of the Royal Society of Arts for August 4 contains the three Cantor Lectures recently delivered before the Society by Mr. C. Ainsworth Mitchell, on "Inks." It is sixty-five years since a communication was made to the Society on this subject—the previous one being a paper by Mr. Underwood in 1857. The lecturer traces the use of inks as far back as 2697 B C., the date of an old Chinese manuscript in which is described the process of making Chinese ink from lamp-black and glue. Iron gall inks are known to have been used in this country as early as the ninth century A D. The use of indigo in blue-black ink was introduced in this country in 1836 by Stephens. Aniline dyes were certainly used in inks more than forty years ago, but their presence in the inks in entries in old family Bibles put forward as proofs that claimants for old age pensions were seventy years old, has several times been fatal to the claim Documents alleged to date from 1719 to 1792 in support of a claim to a baronetcy were proved to be written with ink containing aniline dyes, and therefore were certainly very much more recent The manufacture, properties, sophistication, analysis, and legal aspects of the uses of inks of various kinds were discussed by the lecturer.

We have already referred in these columns to the formation of L'Institut d'Optique and the publication of the *Revue d'Optique* in France These measures have been taken in order that she may manufacture all the optical instruments she requires at home, instead of importing them The July issue of the Bulletin of the Société d'Encouragement pour l'Industrie nationale contains a report on the first two years' work of the Institut According to this report the services of the Institut are likely to be in great demand in the near future, and the accommodation at present provided must be extended More instruments for the practical work of students are required, and time must be allowed in the three years' course for laboratory work It is hoped that the publication of the lecture courses will reduce the time of attendance at lectures and thus provide the additional time required in the laboratory. The researches which the optical industry requests the Institut to carry out are increasing in number and importance and show that it meets a real need

The fourth centenary of the first circumnavigation of the world was celebrated at Guetaria, near San Sebastian, on September 7 Guetaria was the birthplace of Juan Sebastian del Cano, who succeeded to the command of Magellan's expedition after the leader was killed in the Philippines. He returned to Spain in the *Vittoria* on September 6, 1522 An international fleet of twenty-one ships assembled in the bay to take part in the centenary celebrations, at which Great Britain was represented by Rear-Admiral W S Nicholson in H.M.S. *Curaçoa*. A service in the old church was followed by a pageant depicting the scenes which took place on del Cano's return.

The King of Spain laid the foundation-stone of a monument to commemorate the voyage.

AFTER a journey of some 25,000 miles and an absence of almost a year, the *Quest* has returned with the members of the Shackleton-Rowett expedition, and entered Cawsand Bay, Plymouth, on September 15. According to the *Times*, valuable hydrographical work has been carried out in the Antarctic and around South Georgia and Elephant Island, and a large-scale map of Gough Island prepared. The highest point on the latter has been named Mount Rowett. In the Enderby Quadrant a point was reached farther south than the extreme latitudes reached by Biscoe and Bellinghausen, but severe pack-ice prevented the exploration of Enderby Land. Much meteorological data were collected. A new bird of the finch species and a new tree resembling an acacia were discovered on Gough Island. The *Quest* proceeded to Portsmouth, arriving on September 18, and Commander F. Wild received a telegram of welcome from the King, referring to the loss of Sir Ernest Shackleton, the King said: "Your record of achievement and the indomitable spirit displayed by all members of the expedition were in every way worthy of his great example."

PROF. L. BAIRSTOW will deliver a lecture to the Royal Aeronautical Society (at the Royal United Service Institution) at 5.30 on Thursday, October 5, on "The Work of S. P. Langley."

THE twenty-fifth annual Traill-Taylor Memorial Lecture of the Royal Photographic Society will be delivered by Dr. R. S. Clay on Tuesday, October 10, at 8 o'clock. The subject will be, "The Development of the Photographic Lens from the Historical Point of View."

THE following courses of free public Gresham Lectures will be delivered at 6 o'clock at Gresham College, Basinghall Street, E.C.:—on October 17, 18, 19, 20—Astronomy, by A. R. Hinks; on October 24, 25, 26, 27—Physic, by Sir R. Armstrong-Jones; on November 14, 15, 16, 17—Geometry, by W. H. Wagstaff.

MR. E. LEONARD GILL has been appointed by the Civil Service Commissioners to fill the vacant Assistantship in the Natural History Department of the Royal Scottish Museum, Edinburgh. Mr. Gill has already had museum experience in Leicester and Manchester, and for almost twenty years has been in charge of the Hancock Museum at Newcastle-on-Tyne.

A CONFERENCE of representatives of some twenty of the smaller engineering societies has been arranged under the auspices of the Society of Engineers, to be held on September 29 at the Engineers' Club. The object of the meeting is to consider, and if thought advisable, to inaugurate an Association of British Engineering Societies. According to the draft constitution of the proposed Association, there would be no individual members, the constituent societies functioning as such; each society, however, would retain its independence. It is proposed to issue a journal or transactions in which all papers read before constituent societies would be printed and the expenses met by capitation grants from the societies concerned. Further particulars of the meeting and the proposals can be obtained from the Secretary of the Society of Engineers, 17 Victoria Street, S.W.1.

REFERRING to the obituary notice of Dr. Alexander Graham Bell in NATURE of August 12, p. 225, Mr. F. De Land, of the Hubbard Memorial Hall, Washington, D.C., informs us that the Boston newspapers of Monday, November 27, 1876, tell the story of transmitting speech on the previous day about 200 miles from Boston through Portland to Salem; the *Boston Post* stated that the "voice could be heard with considerable clearness after having passed over this great distance. But owing to the unfit construction of the telephones for the duty required of them a distinctness was not attained which would allow a conversation to be carried on." Mr. De Land also states that other records show that *conversation* was successfully transmitted in 1876 a distance of 143 miles. We believe, however, that in the first commercial prospectus of the telephone issued, it was stated that 20 miles was the limit at which the company would establish telephony, on account of distortion; *commercial* telephony at greater distances would have been impossible with the apparatus then in use, though possibly words were transmitted 143 miles so early as 1876.

OUR knowledge of the organs and sense of smell and of odorous substances is defective, and what there is needs systematisation. Mr. J. H. Kenneth has recently published in *Osmics* (Oliver and Boyd, 2s. net) the first instalment of a bibliography of the subject of 500 items which should prove useful to any one desiring to find his way into the scattered literature. There are indexes of subjects and of species of animal.

THE Ministry of Agriculture and Fisheries has recently issued in collected form the leaflets dealing with diseases of animals and insect pests of fruit trees. The two series are now available in bound form ("Collected Leaflets on Diseases of Animals," 1s.; "Collected Leaflets on Insect Pests of Fruit Trees," 10d.). Successful treatment and prevention, whether it be of animal or plant diseases, depends upon early and accurate diagnosis: for the correct identification of the symptoms of any complaint it is necessary to have accurate information available for reference. The leaflets of the Ministry are written with this object in view as well as to supply instructions for the best treatment. The information contained in these two booklets has been brought thoroughly up-to-date, and, in many cases, new and better illustrations than those which accompanied the older leaflets have been provided.

THE reference in NATURE of September 2, p. 324, to the excellent series of wireless telephone receiving sets which are being placed on the market by the Metropolitan Vickers Co., Ltd., contains a statement which, if uncorrected, might lead to misapprehension regarding the completeness of the apparatus sent out by the company. In referring to the simplest of the sets, the remark was made that it was not clear whether the battery was contained in the case. The set in question, however, is fitted with a crystal detector, and therefore no battery is required; and, indeed, this is one of its chief advantages. In the case of the more expensive valve sets, all the necessary batteries are included with the apparatus, for the company makes a special point of the fact that every outfit is sent out complete in every respect.

WE have received from Leslie McMichael, Ltd. (Providence Place, Kilburn), a catalogue of wireless telegraph and telephone apparatus covering a considerable range, and including not only complete receiving sets of various types, but also extensive lists of component parts and accessories from which amateurs and others can make up equipment to cover any requirements on a moderate scale. We notice in particular a very low-priced two-valve receiving set for short wave-lengths which should fulfil the requirements of broadcasting but can easily be converted to longer wave reception and greater sensibility when desired. Some of the apparatus listed has been purchased from the Disposals Board and is offered at favourable prices, and a few items are marked German captured material, transformed as new. A quantity of accessories for transmitting as well as receiving apparatus is included.

Our Astronomical Column.

MARS.—An interesting example of the somewhat unusual atmospheric conditions exhibited on Mars at this apparition is described by E. C. Slipher (Pub. Ast. Soc Pacific, Aug 1922). This was a large white equatorial spot situated at the south end of Margaritifer Sinus; it was about 800 miles long, 400 miles wide, and comparable with the polar caps in brilliancy, though slightly more yellowish. There was no trace of it on July 8; it was very brilliant on July 9; on July 10 it was larger but fainter, and crossed by two greyish streaks; on July 11 it had split into three separate portions, of which only one, to the right of Margaritifer Sinus, remained on July 12. On July 13 and 14 the region had resumed its normal appearance. Whitish patches are frequently seen near the limbs, but they generally disappear near the central meridian, indicating that they are morning or evening mists or hoar frosts. This great spot, on the other hand, persisted in full strength throughout the Martian day. The article is illustrated by drawings and photographs, the latter being on a small scale, but fully confirming the changes in the aspect of the spot, which was probably cloud or mist. Its appearance shows that conditions on the planet's surface are by no means so stagnant as some assert.

Prof W H Pickering contributes an article on the planet to *Popular Astronomy* (Aug.-Sept. 1922). It is in reply to one by Prof Porter, and lays stress on the broad dark band that is visible round the melting polar cap; he gives good reasons for thinking that this is water, not carbon dioxide, and concludes that the day-temperature, even near the poles, is above freezing point, while at the equator it may rise to (say) 60° F. He notes the green colour of the "Maria" after the melting of the polar caps, which he, in common with many astronomers, ascribes to some form of vegetation, another indication of a temperature above freezing point. From the frequent presence of cloud or mist near the terminator, he conjectures that the nights are generally cloudy, which would tend to mitigate the severity of the night frosts. He notes that Prof. Campbell's spectroscopic observation (quoted by Prof. Porter) did not prove the complete absence of water-vapour, but only that its amount was less than a quarter of that in the earth's atmosphere.

THE LAW OF SOLAR ROTATION.—The determination of the law of rotation of the sun is an old problem, first formulated by Carrington, who studied the motions of spots as they moved across the solar disc. As sunspots are confined to middle and low latitudes, the law, based on actual data, was restricted to these latitudes. The spectroscopic method of determination was a great step in advance, because a law could be deduced which could be extended to the solar poles. Spectroscopists have, until recently, been somewhat in difficulty with their results, for determinations at different times by different observers have resulted in formulæ which did not agree. The fact is that a law formulated from observations made at, say, sunspot minimum is not applicable at a sunspot maximum, because the movements of the vapours in the solar atmosphere vary from year to year. This question of the variability of the sun's rotation during a cycle of solar activity was raised last year by Prof. Newall (Mon. Not R.A.S., vol 82, p. 101), and in the current number of the same publication (vol. 82, p. 479) Dr. Halm now clearly shows that "the same law of rotation of the reversing layer can be expected only under similar conditions of activity." He shows a very impressive series of curves, illustrating the angular velocities for about every ten degrees of solar latitude for each year from 1901 to 1914, excluding 1910. In these the angular velocity increases rapidly from sunspot minimum (1901) to sunspot maximum (1905), and then more slowly decreases to sunspot minimum (1913); the amplitude being much more pronounced for high than for low heliographic latitudes. These results are based on observations made at Upsala, Edinburgh, Mount Wilson, and Ottawa.

SUNSPOT IN HIGH LATITUDE.—A small sunspot was noted at Mt. Wilson on June 24 in latitude 31° north, longitude 8° east. No spot has been seen in such a high latitude since December 1919, and it is considered to be the first spot of the new cycle. It will be remembered that the equatorial spots of the expiring cycle continue for a year or more after the commencement of the new one, so that the actual minimum may not be reached till next year. The above spot was of negative polarity, whereas most of the single northern spots in the expiring cycle were positive. This is a further argument, though not a decisive one, for the spot belonging to the new cycle.

Research Items.

The Date of Stonehenge.—In the September issue of *Man* Rear-Admiral Boyle T. Somerville discusses a previous article in that journal by Mr. Stone on the date assigned by Sir Norman Lockyer, through astronomical means, for the building of Stonehenge. He points out in detail the limitations which surround the dating of prehistoric monuments by means of bearings of sunrise or sunset. There are also at Stonehenge two circles, one apparently considerably more ancient than the other. Neither of these stands on the arc of a true circle, and consequently it is not possible to discover the accurate centre, nor any given diameter of either of them. The remains of the earthwork vallum do not lie on parallel lines, nor does either wall appear to be straight. A difference of date of 1000 years is effected by the movement of the observer of only one foot to left or to right of what may originally have been the true point of observation within the circle. The result is that the attempt to date either of the circles at Stonehenge by the azimuth of the midsummer sunrise is useless, as the present condition of ruin of the monument is too great to lay out from the ground-plan of either circle an orientation line of sufficient accuracy. If the orientation towards Silbury Hill can be considered a probability, as it was by Sir Norman Lockyer, the limits of date given by him, namely 200 years on either side of 1680 B.C., are justified for whichever circle to which it related.

Arab Art in America.—The University Museum, Philadelphia, is in the fortunate position of being able to spend largely on additions to its collections. In the March issue of its *Museum Journal*, Mr. G. B. Gordon describes some examples of Arab art which have recently been acquired. Two mosaic fountains of fifteenth-century work are charming, and are appropriately placed in a room decorated with a wonderful wooden door with carved ivory inlay from fourteenth-century Cairo. The ornamentation of this door is singularly beautiful, the style combining small pieces dove-tailed together, the result of the scarcity of large blocks of suitable wood in Egypt. There are also some examples of Rhodian, Damascus, and Samarkand tiles, which are finely reproduced in colour to illustrate the article. Mr Gordon gives some useful notes on the development of Arab art, especially in connexion with the taboo of human and animal forms prescribed in Islam. At Fostat, near Cairo, a rubbish heap in the town, abandoned in the thirteenth century for the present capital, has yielded some curious fragments of early Arab pottery, of which examples are also reproduced in colour.

Origin of Animal Pigments.—That animals in general are, directly or indirectly, dependent upon green plants for their supplies of energy is one of the most widely recognised generalisations of biological science. The importance of chlorophyll in the animal economy, however, seems to be by no means limited to the problem of food-supply. It is extremely doubtful whether chlorophyll is ever actually formed by the animal body itself, but it is very extensively taken in with vegetable food, and then apparently forms the basis from which a large number of animal pigments are built up, including the widely distributed respiratory pigment, hæmoglobin. Such, at any rate, is the finding of Mr. John F. Fulton, Jr., who contributes an interesting paper on "Animal Chlorophyll: its Relation to Hæmoglobin and to other Animal Pigments" to the current number of the *Quarterly Journal of Microscopical Science* (vol. 66, Pt. II). It would appear from these results that a vast number of animals are dependent upon green plants for their ability to carry on the function of respiration as well as that of nutrition.

Sources of Vitamin A.—In the *Biochemical Journal* (vol. xvi., No. 4) a paper appears under the names of H. L. Jameson, J. C. Drummond, and K. H. Coward, giving an account of the work in which Dr. Jameson was engaged at the time of his death. Previous work by the other two authors had shown that vitamin A is produced in green plants by the action of light. Animals are apparently unable to make it for themselves, and since the liver of fishes is one of the best sources of this vitamin, it was of interest to follow the course of its transfer to this place. In the present paper it is shown that a pure culture of the diatom Nitzschia produces the vitamin under the action of light. Various molluscs were also found to contain it in considerable amounts. In a further paper in the same number of the journal, Prof. Drummond, Dr. Zilva, and Miss Coward show that the small organisms of animal nature making up the plankton on which small fish feed contain vitamin A in abundance, no doubt derived from the diatoms on which the plankton feed. Thus the cycle in marine life is complete. Whether this vitamin is identical with that preventing the onset of rickets is made somewhat doubtful by a paper in the *Journal of Biological Chemistry*, vol. 53, p. 293, by McCollum, Simmonds, Becker, and Shipley, in which it is shown that the vitamin A of cod-liver oil can be destroyed without depriving the oil of the substance which causes utilisation of calcium and its deposition in the bones. It may be that it is this "vitamin" that is produced in the human infant under the action of light.

Anomalous Storm Tracks.—A communication is made on this subject to the *U.S. Monthly Weather Review* for March by Mr. E. H. Bowie of the U.S. Weather Bureau. The author criticises the explanation of the paths of cyclones given in the text-books, and remarks that it would simplify the work of forecasters if cyclones behaved in an orderly manner. The paths are shown of five exceptionally erratic cyclones, and especial care has been taken to ensure the accuracy of the charted positions of the storm centres. The erratic paths given traverse the eastern United States; one storm was of West Indian origin. Each of the tracks formed one or more loops, and in forming the loop the turning in all cases was counter-clockwise. Some notes on the erratic paths of the storms are added by Prof. A. J. Henry, chiefly with the object of stimulating discussion. He notes that the temporary blocking in the path of the cyclone takes place in the neighbourhood of water surface, and in each case of temporary blocking, except in that of the West Indian storm, pressure rose over the Canadian Maritime Provinces.

Climate and Photography.—An article by Mr. H. G. Cornthwaite on this subject appears in the *U.S. Monthly Weather Review* for March. The wide variations in the strength of daylight with the time of day, season of the year, conditions of the sky, and with latitude and altitude, as well as the effects of temperature and humidity on photographic and chemical processes, are recognised and discussed. The actinic light is naturally brightest when the sun

is at or near the zenith, and it dims rapidly with increased obliquity of its rays. The seasonal variation due to this cause is said to be too often overlooked or underestimated by amateur photographers, the strength of the light being about twice as great in summer as in late autumn or winter. It is mentioned that during heavy rainfall the light is photographically stronger than in densely cloudy weather without rain, due to the light reflected from the falling raindrops. Tropical daylight is asserted to be about twice as strong photographically as summer daylight in latitude 40°, and about four times as bright as winter daylight at this latitude. The light is much brighter along the sea coast than inland. Chemical activity in developing and fixing processes is greatly increased with high temperatures, and correspondingly retarded with low temperatures. Photographic films and prints may be subjected either to high temperatures or high humidity without excessive deterioration, but not to both in combination. Both prints and films are said to deteriorate rapidly in the moist tropics, but those developed and fixed under tropical conditions have a greater permanence in the tropics than those developed and printed in the temperate zone and subsequently taken to the tropics.

ELECTRICAL RESISTIVITY OF STEELS UNDER STRESS.—The recent researches of Bridgman have shown that under hydrostatic pressure the resistivity of steels decreases, while the earlier work of Tomlinson on stretched steel wires showed that under tension less than the elastic limit the resistivity increased. According to the May issue of the Science Reports of Sendai University, Mr. Sin-iti Fukuta has, under the direction of Prof. Honda, carried the observation of the effect of tension on resistivity beyond the elastic limit, and has succeeded in showing that up to stresses of the order of 5000 kilograms per sq. cm., steels with various carbon contents increase in resistivity $1 \cdot 14 \times 10^{-6}$ per cent. per kilogram per sq. cm. of tensile stress, the proportionality continuing past the shoulder of the stress-strain curve. In all cases about 90 per cent. of the observed change of resistance of the specimen was due to its elongation and cross contraction.

GLASS RESEARCH.—Volume iv. of "Experimental Researches and Reports" has recently been published by the Glass Technology Department of the University of Sheffield. It comprises a series of reports by Dr. W. E. S. Turner and his staff, principally on the influence of aluminium on sodium and sodium calcium trisilicate glasses. Aluminium is shown in the first paper, No. VII., to facilitate manipulation in lamp-working and to assist in preventing devitrification. The second paper on the effect of aluminium on the annealing temperature is less convincing, as it neglects questions of time and rates of cooling. Pelouze's conclusion that as aluminium is substituted for sodium the density increases, is reversed in paper IX., density and refraction both appear to diminish. Careful stirring has evidently been necessary to detect the small variations recorded. In determining the thermal expansion effect of silica and sodium oxide in sodium silicate glasses, a silica factor value very different from that of Schott has been obtained. In the next paper, No. XV., the effect of aluminium on thermal expansion is considered, but further research is evidently required. Two of the most practical papers deal with the relative advantages and disadvantages of limestone, burnt lime, and slaked lime in common glass batches containing soda ash and salt cake. The shrinkage, porosity, and other properties of British fireclays are discussed in paper XXIII. Comparison is made with one foreign clay only, the German Grossalmerode. In view of the present conditions it might have been well to include several of the French clays which compare favourably with Grossalmerode. Following two papers on lime-magnesia glasses, a general report on glass and one on the refractory materials, both by Dr. Turner, are reprinted. The glass industry is to be congratulated upon its close association with the University of Sheffield and the Society of Glass Technology.

PHOTOGRAPHIC SENSITOMETRY AND TESTING.—The Washington Government Printing Office has issued No. 439 of the Scientific Papers of the Bureau of Standards on the "Sensitometry of Photographic Emulsions and a Survey of the Characteristics of Plates and Films of American Manufacture," by Raymond Davis and F. M. Walters, jun. For several years the Bureau of Standards has made measurements of the characteristics of photographic light-sensitive materials, aiming at uniformity in the standardisation of methods, so that the results by various workers may be directly comparable. The present paper gives details of the principles involved in photographic sensitometry and testing generally as introduced by Hurter and Driffield and published over and over again during the last thirty years. Perhaps it is desirable to restate them to render the paper more complete. The methods of the Bureau are more original. Their light source is a 6 to 8 volt Mazda C automobile headlight with a special blue glass filter, giving 2·73 candle-power and the colour of average yearly noon sunlight at the latitude of Washington. The principal other deviation from H. and D. methods is that the Bureau of Standards defines the speed of a plate as 10 divided by the inertia, instead of 34 divided by the inertia as adopted by Hurter and Driffield to fit in with their actinometer. For colour sensitometry a replica grating is used with a slit 2 inches long, and the exposure is graduated by a disc with suitably curved apertures that is rotated close in front of the slit. The methods of making other tests are fully described. Appended are 86 charts, each dealing with a single plate and giving three characteristic curves representing the result of development for 3, 6, and 12 minutes respectively, a contrast development curve, a fog contrast curve, the fog being exclusive of the glass and gelatine, a spectrogram showing colour sensitiveness, exposure factors for several colour filters, speed, extent of the straight part of the characteristic curve, and the resolving power estimated by a standardised method. Only sensitive materials made in the United States, and practically all of these, are discussed.

SEPARATION OF ISOTOPES OF LEAD.—In the Scientific Proceedings of the Royal Dublin Society for August (vol. xvii. N.S. No. 6), Drs. T. Dillon and R. Clarke and Mr. V. M. Hinchy describe some preliminary experiments on the separation of the isotopes of lead by a chemical method. The process is based on the reaction between lead chloride and an organo-magnesium compound:

$$2PbCl_2 + 4MgRX = PbR_4 + 2MgCl_2 + 2MgX_2 + Pb.$$

Hoffmann and Wolf in 1907 had already found that when lead chloride containing radium-D reacted with magnesium phenyl bromide, most of the radio-activity was found in the metallic lead separated by the above reaction, and this was confirmed. With the two portions of lead separated, the atomic weights 207·1 and 207·3 or 207·4 were found, and it is considered that the different isotopes of lead are not identical in their chemical properties in the reaction chosen. Further experiments are in progress.

Potato Trials at Ormskirk.

SIR DANIEL HALL, Chief Scientific Adviser of the Ministry of Agriculture, presided at the public inspection at Ormskirk on August 24 of the eighth series of annual trials of new potato varieties for immunity from Wart Disease (*Synchytrium endobioticum*). In addressing the important gathering of growers and scientific workers, Sir Daniel expressed the view that the disease must inevitably spread over the whole of Great Britain. The only known protection against the disease is to plant varieties which are immune from its attacks; unfortunately the most popular of the varieties at present grown are not immune. The production of new immune varieties with good cropping, cooking, and keeping qualities is therefore essential, and it was with the view of enabling raisers to ascertain whether their new productions would resist the disease that these trials were begun in 1915. In that year 94 stocks were sent for test; the trials have been largely developed by the Ministry of Agriculture, and since 1920 have been carried out at the Potato Testing Station of the National Institute of Agricultural Botany. This season 2500 stocks were planted. In an attempt to keep the spread of the disease within bounds the Ministry issues annually a list of new varieties which have proved immune in the trials. Only listed varieties may be planted in infected soil, or sent away from infected areas for seed purposes. Before a variety is regarded as immune it must have been grown at Ormskirk for two consecutive seasons without succumbing. Supplementary one-year trials of small stocks (not exceeding ten tubers) of seedlings are conducted for the information of raisers, but these trials are not taken into account by the Ministry in drawing up the list of immunes.

It is apparent from the results of the last two seasons that the rainfall affects the incidence of the disease. In the dry summer of 1921 the disease appeared very late, and its attacks were less severe; this season, with much rain, the disease has appeared earlier and is very marked. Of the 91 new stocks that are being tested for the second season, 19 have so far succumbed, though they escaped last year.

There are 123 stocks under trial for the first time this season; 58 have already succumbed and 48 cannot be distinguished from previously existing varieties. The number of varieties entered as new but in fact identical with older varieties is, however, much smaller than in previous years owing to the activities of the Synonym Committee of the National Institute of Agricultural Botany. The one-year seedling trials occupy 1700 of the 2500 plots, and 500 are planted with stocks of established varieties for demonstration purposes.

The Institute is also conducting, for the second year, trials to establish the relative dates of maturity of nine important first early varieties, and the influence of source of seed on date of maturity and yield. The trials are composed of three chequer boards, one consisting of all 9 stocks drawn from 8 different districts, one of all 9 stocks from one district, and the third of one stock drawn from all 8 districts. The results should also be of value in indicating the most accurate method for conducting yield trials.

International Reunion of Chemists at Utrecht.

ON June 21, 22, and 23 there was held at Utrecht an international reunion of chemists, which was organised by Profs. Ernst Cohen, H. R. Kruyt, and P. van Romburgh, of the University of Utrecht. Among those also present may be mentioned:—Abel (Vienna), Backer (Groningen), Baly (Liverpool), Billiter (Vienna), Bjerrum (Copenhagen), Bodenstein (Hanover), Blanksma (Leiden), Bredig (Carlsruhe), Brönsted (Copenhagen), Centnerschwer (Riga), Dennis (Ithaca, N.Y.), Donnan (London), Dubsky (Brunn), Emich (Graz), Hahn (Berlin-Dahlem), Holleman (Amsterdam), MacInnes (Cambridge, Massachusetts), Jaeger (Groningen), Jorissen (Leiden), Kailan (Vienna), Klemenc (Vienna), Lewis (Liverpool), Noyes (Urbana, Illinois), Petersen (Copenhagen), Pfeiffer (Bonn), Piccard (Lausanne), Pregl (Graz), Reinders (Delft), Schenck (Munster), Schilow (Moscow), Schlenk (Berlin), Šunek (Brunn), Skrabal (Graz), Stock (Berlin-Dahlem), Walden (Rostock), Wegscheider (Vienna), Wieland (Freiburg in Breisgau), and Winther (Copenhagen).

During the scientific meetings a number of very interesting papers were read, which gave rise to good discussions. Among these may be mentioned the following: photochemical catalysis (Baly), the photochemical combination of hydrogen and chlorine (Bodenstein), free radicals (Walden); contributions to the chemistry of the free radicals and the variable affinity-value of the carbon linking (Schlenk); free radicals (Wieland); positive and negative valence (Noyes); the preparation and properties of metallic germanium (Dennis), absorption colours of the second order (Piccard), and adsorption and distribution (Schilow).

The chemists attending the meeting received the heartiest of welcomes and the most lavish hospitality from their Dutch colleagues, who arranged a series of lunches, dinners, and excursions. Few of those who were present will ever forget the splendid hospitality of Holland, the excellence of the arrangements, and the atmosphere of good fellowship which characterised the meeting.

On the afternoon of the second day a reception was given by the Dutch Chemical Association, while on the afternoon of the last day the members were invited to tea by Count Dr. van Lynden van Sandenburg, Governor of the Province of Utrecht, and Countess van Lynden van Sandenburg. The meeting concluded with a banquet at the Badhotel, Baarn, which was preceded by a visit to the beautiful Botanic Gardens of the University of Utrecht.

The heartiest thanks of all the chemists who attended the meeting are due to Prof. Ernst Cohen, who acted as a most genial and efficient president, to his collaborators, and to all those in Holland who subscribed so liberally towards the expenses of the reunion. It was felt by all present that Holland had done in the most graceful way a noble piece of work towards the promotion and restoration of that international friendship of science which is of such vital importance for the world.

F. G. D.

Summary of the Theory of Relativity.

By Prof. H. T. H. PIAGGIO, University College, Nottingham.

I. BREAKDOWN OF OLDER THEORIES.—The older electromagnetic theory of moving bodies did not agree with experiment, or even with itself. For example, the theory of a magnet moving in a straight line towards a fixed conductor gave results quite different from those of the theory of a conductor moving in a straight line with the same velocity towards a fixed magnet. Yet experiment showed that the results should be the same, depending only on the *relative* velocity. Again, the æther was assumed to be at the same time quite unaffected by the earth's motion (to explain aberration), partly affected (to explain Fizeau's water-tube experiment), and entirely affected (to explain the experiments of Michelson and Morley, Lodge, Rowland, Rayleigh and Brace, Trouton and Noble, and others).

II. FUNDAMENTAL ASSUMPTIONS OF EINSTEIN'S RESTRICTED THEORY (1905).—This takes over Maxwell's theory so far as it applies to bodies at rest relative to the earth and deals with other systems by the two following assumptions.

(1) All electrodynamical and optical equations which hold for a system S hold also for another system S′ which, relative to S, moves with uniform velocity v in a straight line.

(2) Light is propagated in a vacuum with a velocity c which appears the same for observers in S and S′.

Kinematical deductions from these assumptions.—These imply that the measures of time and space in S and S′ must be such that

$$x^2+y^2+z^2-c^2t^2=x'^2+y'^2+z'^2-c^2t'^2,$$

from which, taking the corresponding axes in each system to be parallel and the relative velocity to be along Ox (or Ox'), we can prove that

$$x'=\beta(x-vt),\ y'=y,\ z'=z,\ t'=\beta\left(t-\frac{vx}{c^2}\right)$$

$$\text{where } \beta=\left(1-\frac{v^2}{c^2}\right)^{-\frac{1}{2}} \quad . \quad (A),$$

hence two observers, one in S and one in S′, will *each* imagine

(i.) that a rod along Ox (or Ox') in the other's system has contracted in the ratio β : 1;

(ii.) that the other's clocks (supposed controlled by light signals) lose, taking β seconds instead of 1 for a beat,

(iii.) that the events which the other takes as simultaneous are not so.

What they will agree about is the velocity of light, c, their own relative speed, and the *interval* between two sets of values, x, y, z, t, for two events, this *interval* being defined as

$$\sqrt{\{c^2(t_2-t_1)^2-(x_2-x_1)^2-(y_2-y_1)^2-(z_2-z_1)^2\}},$$

which may be written,

$$\sqrt{\{c^2dt^2-dx^2-dy^2-dz^2\}}.$$

It is generally denoted by ds.

From equations (A) $\dfrac{dx'}{dt'}=\dfrac{\dfrac{dx}{dt}-v}{1-\dfrac{v}{c^2}\dfrac{dx}{dt}}$, so that if the velocity of the body moving along Ox (or Ox') is V in the system S and V′ in the system S′

$$V'=\frac{V-v}{1-\dfrac{vV}{c^2}},\ \text{or}\ V=\frac{V'+v}{1+\dfrac{vV'}{c^2}}.$$

This is confirmed by Fizeau's water-tube experiment, and (it is claimed) by Majorana's moving mirror experiment. From this formula we see that by combining two velocities V′ and v, each of which is smaller than c, we obtain a velocity V which is always smaller than c. (The statement that "*no velocity can exceed c*" is too sweeping; the velocity of light in a thin metal prism exceeds c.)

Electrodynamical deductions from these assumptions.—Transforming Maxwell's equations for free space in which electrons move with velocity V along Ox we get from assumption (1) and equations (A) that

$$\left.\begin{aligned} &E'_x=E_x, && H'_x=H_x\\ &E'_y=\beta\left(E_y-\frac{v}{c}H_z\right), && H'_y=\beta\left(H_y+\frac{v}{c}E_z\right)\\ &E'_z=\beta\left(E_z+\frac{v}{c}H_y\right), && H'_z=\beta\left(H_z-\frac{v}{c}E_y\right)\\ &\rho'=\beta\rho\left(1-\frac{vV}{c^2}\right). \end{aligned}\right\} \quad . \quad (B).$$

The expression for ρ' gives the remarkable result that the charge on an electron appears the same in both systems. From these we can deduce:

(i.) Doppler's effect in the modified form—

$$f'=f\left(\frac{1-\dfrac{v}{c}}{1+\dfrac{v}{c}}\right)^{\frac{1}{2}},$$ where v is the relative velocity in the line of sight, f and f' the frequencies;

(ii.) a modified law of aberration;

(iii.) the force exerted by light on a moving mirror;

(iv.) the electric and magnetic fields due to a uniformly moving electron

The differences between these forms and those given by older theories are too small to be detected by experiment

Dynamics of an electron (slowly accelerated).—With the *additional assumption* that every electron has a constant m associated with it, such that *force = m × acceleration* at the instant when the electron is at rest in the system of co-ordinates used (and only at that instant), we deduce that in any other system the equations of motion are

$$\left.\begin{aligned} m\beta^3\frac{d^2x}{dt^2}&=eE_x,\\ m\beta\frac{d^2y}{dt^2}&=e\left(E_y-\frac{v}{c}H_z\right),\\ m\beta\frac{d^2z}{dt^2}&=e\left(E_z+\frac{v}{c}H_y\right), \end{aligned}\right\}$$

where e is the charge on the electron and the axis of x is taken in the direction of its velocity v. The second and third of these equations are confirmed by Bucherer's experiments

If, with Lorentz, we take the right-hand sides as the components of the force, and retain the old law *force = mass × acceleration*, we find it necessary to speak of a longitudinal mass $m\beta^3$ and a transverse mass $m\beta$.

But we may rewrite the left-hand sides in the symmetrical form $\dfrac{d}{dt}\left(m\beta\dfrac{dx}{dt}\right)$, $\dfrac{d}{dt}\left(m\beta\dfrac{dy}{dt}\right)$, and $\dfrac{d}{dt}\left(m\beta\dfrac{dz}{dt}\right)$.

This suggests the definitions:

mass (M) = mass at low speeds × β (both for longitudinal and transverse mass);

momentum = mass × velocity;

force = rate of change of momentum.

Defining work in the usual way from force and displacement, we can further deduce:

Work done on an electron = increase of its kinetic energy, provided that kinetic energy is defined as Mc^2 + a constant = $m\beta c^2$ + a constant.

If we take the constant equal to $-mc^2$, this new definition reduces to $\frac{1}{2}mv^2$ approximately for small values of v/c. From Maxwell's equations we can derive four relations for an isolated system of electrons which

may be interpreted as the conservation of momentum and of energy provided that the momentum and energy of the electrons are defined as above, and that the momentum and energy of the field are included, the momentum of the field per unit volume being defined as Π/c^2, where Π is Poynting's vector. Observations on the spectral lines of hydrogen, and Guye and Lavanchy's experiments on cathode rays, confirm these results.

III. FUNDAMENTAL ASSUMPTIONS OF EINSTEIN'S GENERALISED THEORY (1915).—(1) For an infinitely small region of space and time, axes may be chosen so that the restricted theory is true in that region. This implies that for two events there exists a certain absolute quantity, the interval ds, which, by a *suitable* choice of co-ordinates, may be expressed as before, but which in a general system of co-ordinates, $x_1\ x_2\ x_3\ x_4$ (these being arbitrary functions of $x\,y\,z\,t$), take the form $\sqrt{(\Sigma_r\Sigma_s g_{rs}dx_r dx_s)}$, where r and s take all values from 1 to 4, and the g's are functions of $x_1\ x_2\ x_3\ x_4$.

(2) All physical laws must be expressible by means of equations which are valid for all co-ordinate systems. That is to say, the equations are covariant, or unaltered in form, for the most general transformation (not necessarily linear). Newton's law of gravitation and all other laws that do not satisfy this condition are to be modified so as to conform with it.

(3) *The Principle of Equivalence.*—A gravitational field of force at a point or infinitely small region is exactly equivalent to a field of force introduced by a transformation of the co-ordinates of reference, so that by no possible experiment can we distinguish between them. (Eddington pointed out that the assumption is made for phenomena which depend on the g's and their first differential coefficients, and in general it will *not* apply to those involving second differential coefficients.)

(4) The path of a particle in a gravitational field is such that $\delta\int ds=0$. (For the case when there is no gravitation this reduces to Newton's first law of motion.) This assumption reduces particle dynamics to something like the geometry of geodesics on surfaces, except that we have four independent variables instead of two.

(5) Although the coefficients in the expression for ds^2 are capable of infinitely many forms, according to the system of co-ordinates used (just as in measurements on a surface the square of the shortest distance on the surface between two points can be similarly expressed in many forms corresponding to the choice of the independent variables), yet these g's are not quite arbitrary functions of the co-ordinates, but satisfy a set of partial differential equations (analogous to those which for a surface express intrinsic properties of that surface). These differential equations are *assumed* to be of a certain particular form, known as those expressing the vanishing of the *contracted Riemann-Christoffel* tensor. (A tensor may roughly be defined as a generalised vector. If all its components vanish in one system of co-ordinates, they all vanish in any other system.) This assumption is not quite as arbitrary as it looks, for it is the second simplest set which is of the covariant form required by assumption (2). The simplest set of all corresponds to the absence of any gravitational field.

(6) The energy of a gravitational field exerts gravitating action just like ordinary masses. This assumption leads to equations which may be interpreted as implying the conservation of momentum and energy, including contributions due to the gravitational field (and to the electromagnetic if present).

Mathematical Deductions from these Assumptions.—(a) *Formulæ for the Interval.*—By solving the differential equations the g's may be obtained. The number of solutions is infinite. For a single heavy mass, choosing the units so that c and the gravitational constant are unity,

Schwarzschild gave

$$ds^2=\left(1-\frac{2m}{r}\right)dt^2-\left(1-\frac{2m}{r}\right)^{-1}dr^2-r^2d\theta^2-r^2\sin^2\theta d\phi^2.$$

F. W. Hill and G. B. Jeffery gave

$$ds^2=\frac{\left(1-\frac{m}{2r}\right)^2}{\left(1+\frac{m}{2r}\right)^2}dt^2-\left(1+\frac{m}{2r}\right)^4(dr^2+r^2d\theta^2+r^2\sin^2\theta d\phi^2).$$

and Painlevé has given a great variety.

(b) *Perihelion of Mercury.*—From any of these forms and assumption (4) we can by the Calculus of Variations determine the orbit of a planet. The orbits so deduced differ very little from those calculated on the Newtonian laws. The only difference big enough to be observed is that for Mercury. Leverrier estimated that the older theory differed from observation by about 43″ per hundred years. Einstein's theory accounts for these 43″. (But Grossmann (1922) has recalculated the old discrepancy as 38″, not 43″.)

(c) *Deflection of Ray of Light by Sun's Gravitational Field.*—The rays should be slightly curved, as if the gravitational field round the sun were a converging lens, thus making stars on opposite sides of the sun appear farther apart than when the sun is in another part of the sky. The result of the measurements made during the solar eclipse of May 29, 1919, agreed very closely with Einstein's predictions. This is strong evidence in support of Einstein's modification of the Newtonian law, as on the old law the deflection should be only half the amount predicted by Einstein and actually observed.

(d) *Spectral Shift.*—Einstein believes that the formula for ds^2 implies that the spectral lines in the light coming to us from the surfaces of big stars should appear shifted towards the red end of the spectrum. Eddington and others think it possible that this argument may be founded on an assumption which may be rejected while the rest of the relativity theory is retained. Grebe and Bachem (Bonn) claim to have observed the predicted effect, and so do Perot and Buisson and Fabry; St. John claims to have shown that it does not occur, but his results have been doubted. The experimental difficulties are enormous.

(e) *Apparent Contraction of a Rod placed radially in a Gravitational Field.*—Einstein deduces this from the formula for ds^2 and also deduces that there is no such tangential effect. Painlevé (1921) strongly objects to these deductions and points out that by taking other forms of ds^2 we can reject these conclusions, while retaining all the verifiable results of the theory. If Einstein's views are correct, Euclidean geometry (*e.g.* Pythagoras's theorem) is not exactly true for measurements made in a gravitational field. It will be replaced by Riemann's geometry.

IV. EINSTEIN'S COSMOLOGICAL THEORY (1917).—The leading feature of this is that our universe, *as measured by material rods or light rays*, is finite, so that a ray of light will never get more than a certain distance from its starting-point. However, he is willing to admit that other universes may exist outside this limit, but such that their light can never meet ours. Eddington and others regard this theory rather unfavourably.

V. EINSTEIN'S VIEWS ON THE ÆTHER (1920).—Space is endowed with physical qualities. In this sense, therefore, there exists an "æther." Without it there would be no propagation of light. But this

æther may not be thought of as endowed with the physical properties of material media. It must not be considered as either fixed or moving. No explicit use of any conception of the æther is made in the theory of relativity. It is difficult to see what use could be made of the above views, which are chiefly negative The phenomena of the gyroscope and Foucault's pendulum (and Sagnac's optical experiment), which on the Newtonian ideas are attributed to absolute space, are attributed by relativists to the æther or the effects of the fixed stars—which is rather unconvincing.

VI. WEYL'S EXTENDED THEORY (1918)—Whereas Einstein's interval depends only upon gravitational phenomena (although Maxwell's equations and all electromagnetic effects fit into the framework thus constructed), Weyl assumes that the length of the measuring rod depends upon the route it has taken in the neighbourhood of electromagnetic fields. When these are present, the interval is no longer a definite quantity (thus weakening the argument for the spectral shift). This theory accounts for Maxwell's equations and introduces Einstein's cosmological term in a natural way, and adds the law of conservation of electricity to those of conservation of momentum and energy. On the other hand, it introduces great complexity into geometry and appears to imply the impossibility of metrology, beyond a certain—very high—degree of accuracy There is no experimental confirmation. Einstein does not accept it. Eddington (1921) has generalised Weyl's mathematics, but says, "Einstein's postulates and deductions are exact. The natural geometry of the world . . . is the geometry of Riemann and Einstein, not Weyl's generalised geometry or mine."

VII. PAINLEVÉ'S SEMI-EINSTEINIAN THEORY OF GRAVITATION (1922)—This retains Euclidean geometry and the old ideas about space and time. By axioms which are somewhat similar to those of Einstein, but which make no reference to the restricted theory, Schwarzschild's form of ds^2 and the verified astronomical results are obtained.

Kitchen Ranges.

THERE is probably no more difficult problem presented to the heating engineer than the kitchen range So complicated is it that it would appear that no single appliance could possibly be constructed to suit every house or even any large number of houses, and that each installation would have to be adapted to the requirements of the special household For example, a working-man's cottage usually requires only one fire, which, in the absence of a gas cooker, must satisfy the quadruple duty of heating the room, the oven, the hot-plate and the water, whereas a better class of house might use, and with greater economy, a gas cooker and a coke boiler for the supply of hot water and radiators Then, again, in an ordinary household, cooking is an operation occupying two or three hours per day only, while hot water is likely to be required at any moment throughout the day. Heating of the rooms is required continuously all day in winter, but not at all in summer The inevitable consequence of such an intermittent demand is a low efficiency

We have before us two important pamphlets embodying the researches of Dr. Margaret Fishenden and Mr A H Barker carried out under the auspices of the Fuel Research Board[1] Dr. Fishenden has restricted her investigation to the comparative efficiency of ranges fired with ordinary bituminous coal and those heated with the special coke cakes (low temperature coke) produced by the Fuel Research Station at E Greenwich. She finds that low temperature coke yields a greater proportion of total heat for radiation or for water heating than bituminous coal, while for oven heating the coke compares less favourably with coal, the advantage of coke being largely due to radiation effects. She finds, moreover, that in an open kitchen range with back boiler about 17 per cent. of the heat of the coal is used for hot water, and in modern designs it varied from 13 to 19 per cent., a result rather higher than that found by Mr. Barker.

It is unfortunate that Dr. Fishenden's experiments do not include ordinary coke, as the low temperature coke prepared by the Fuel Research Board is a commodity not yet on the market and unlikely to appear there, as it is obviously too costly to compete at present with either coal or coke. The report of Mr. Barker (who is lecturer on heating and ventilating engineering at University College, London) deals in a very comprehensive fashion with the whole subject of kitchen ranges, and the results of a large number of practical tests on old and new designs using coal, coke, and gas as sources of fuel. The introduction to the report contains the following statement: "In the design of British cooking ranges, attention has hitherto been mainly devoted to securing cheapness of construction and convenience of use. Economy in fuel consumption has only played a minor part in determining the different types in use The shortage and high price of coal have, however, emphasized the necessity for fuel economy and, consequently, of an examination of the efficiency of British kitchen ranges. . . . The strong prejudice in favour of an open-fronted fire appears to be peculiar to this country. In most other countries a cooking range fire is usually closed. . . . In view, therefore, of the scarcity and high price of coal at the present time, it appears to be a matter for serious consideration whether steps should not be taken to encourage the more general adoption in this country of ranges which are more economical in fuel consumption than those of ordinary British design."

In his general summary Mr Barker has arrived at the following conclusions: that the general efficiency of all ranges on the market at the present time is low, the actual oven efficiency ranging from 0.75 to 5 per cent., the usual being about 2 per cent, that of the hot water supply from 7 to 17 per cent. or usually 11 per cent, and the hot plate from 1 to 12 per cent or generally below 6 per cent. He estimates that the modern type of range wastes 85 per cent. of the fuel in heating the air of the kitchen (about 30 per cent.), by absorption in the brickwork (about 30 per cent), and lost in the flue gases (about 25 per cent). Economy may be effected by not setting ranges in brickwork, by preventing leakage of cold air into the furnace and flues, and by doing away with the hot-plate or covering it when not in use, and also the oven door, with non-conducting material. He admits, however, that these losses are unavoidable if the present convenience and cheapness of the ordinary range are to be retained and one fire made to serve so many different purposes. But if the efficiency is considered irrespective of convenience, cheapness,

[1] (1) The Efficiency of Low Temperature Coke in Domestic Appliances, by Dr Margaret W. Fishenden. Fuel Research Board, Technical Paper No 3 London H M Stationery Office, 1922. 9d net
(2) Tests on Ranges and Cooking Appliances, by A H Barker. Fuel Research Board, Special Report No. 4. London: H.M. Stationery Office, 1922. 2s. 6d net.

and space, then it would be necessary to have separate fires for oven, hot water, and hot-plate. This is obviously impracticable; but, on the other hand, in a well-insulated oven heated over a small fire without excess of air by leakage, an efficiency of 30 per cent. might easily be achieved, and, he adds, "there is no reason why a whole dinner could not be cooked in such an oven with 2 lbs. of fuel." But beyond 40 or 50 per cent efficiency in the oven it is impossible to go, and the ideal conditions can be attained only by electrical heating.

The adoption of an independent boiler would raise the efficiency of the fuel for the hot water supply from an average of 8 to 10 per cent. to 40 to 45 per cent., a figure which Dr. Fishenden gives for a coke-fired boiler. On the other hand, for a small household such a boiler is too large, and a small boiler is difficult to fire and keep alight, especially with coke.

The principal cause of loss from a hot water equipment is not so much the low efficiency of the apparatus as the subsequent loss of heat from the storage vessel by radiation. Hot water should be generated when it is required, and this can be done only by gas as in the gas geyser, which is efficient and useful though clumsy and dangerous. If the appliance can be so arranged that the fire can be lighted and burn itself out, a sufficient supply of hot water would be produced for a whole day's use provided the heat was not allowed to escape by proper insulation

The report contains a lot more useful, practical information as to the method of installation, but perhaps the most significant and encouraging part of the report is the improvement in efficiency which Mr. Barker has himself effected in ranges of his own design whereby he has reduced the fuel consumption by about 70 per cent It is to be hoped that this new type of range will soon be placed on the market. J. B. C.

University and Educational Intelligence.

LEEDS —The hon degree of Doctor of Science has been conferred on the following Sir Charles Scott Sherrington, G B E, president of the British Association, the Duc de Broglie, Institut d'Optique, Paris, Dr C G Joh Petersen, director of the Danish Biological Station, Copenhagen, and Prof P. Weiss, director of the Institut de Physique, University of Strasbourg.

LONDON —Mr. T. A. Stephenson of Kingswood School and University College, Aberystwyth, has been appointed assistant in the department of zoology and comparative anatomy at University College.

A programme of public lectures, admission to which is free and without ticket, to be delivered at University College during the coming term, has been issued It includes lectures on social life in Egypt by Prof Flinders Petrie, on recent excavations in Malta by Miss M. A Murray, on the beginnings of science by Prof. G Elliot Smith, on the nature of intelligence by Prof. C. Spearman, and a series of lectures on phonetics, including one on the nature and reproduction of speech sounds by Sir Richard Paget. At King's College there will be a course of ten lectures by Prof. H. Wildon Carr, commencing on October 5, on the new method of Descartes and the problems to which it gave rise, five lectures by Miss Hilda D. Oakeley on the Stoic philosophy, commencing on November 9; one lecture on October 9, at 5.30, by Prof. G B. Jeffery on Einstein's theory of relativity; six lectures, commencing October 17, on modern hydro-electric engineering practice by E. M. Bergstrom; and three lectures, commencing November 28, on the fuel problem from an engineering standpoint by Dr. C. H. Lander. Complete lists of the lectures can be obtained on application, enclosing a stamped addressed envelope, to the secretary of the college in question.

AN article on "The New University of London," by T. Ll. Humberstone, appears in the *English Review* for September After showing that so far back as the twelfth century there existed in London all the necessary elements for the formation of a great university, and speculating as to the reasons why, nevertheless, it was not until the nineteenth that one came into being, the writer describes the establishment of the University of London as an examining board in 1836 and its reconstitution as a teaching university in 1900. Of the "third incarnation," now inaugurated with the gift by the Government of eleven and a half acres of land adjoining the site of the British Museum, he writes "Our task is to open a new Pierian spring to quench a world-thirst": the new university of London is destined to play a great part in the re-establishment of the cosmopolitan spirit which, under the influence of the Roman Church, tended in the Middle Ages to make Europe a single nation. Time will show whether these aspirations, stimulated by Mr Fisher's speech at University College last February, can be realised. Meanwhile there is one obstacle, easily removed, to which attention was directed at the recent conference at Basle of delegates from British and Swiss universities There London's policy in regard to the admission of foreign students was criticised as illiberal. Why, it was asked, should London insist on verifying, by a special matriculation examination, the attainments of students who hold certificates qualifying for admission without further examination into the universities of Switzerland, and implying matriculation standards of attainment in the subjects of the London examination? Cambridge has lately adopted a comprehensive exemption formula recognising the sufficiency of the standards implied by such foreign certificates, and it was hoped that London would do likewise.

THE University of Colorado Catalogue, 1921–22, issued in March 1922 with announcements for 1922–1923, presents several interesting features, exemplifying recent developments in American State universities. The University Extension Division, organised in 1912, "aims to make the campus of the university co-extensive with the State, in keeping with the new idea that a State university exists for all the people and not for a favoured few alone" It has a Faculty comprising 12 administrative and secretarial officers, besides professors and instructors in the various university departments, and a non-resident staff numbering 31. Among its varied activities are: correspondence courses, in which form one-fourth of the work for the A B degree may be taken; class instruction, more or less on the lines of our university extension lecture courses, but qualifying equally with courses taken in the university towards degrees; courses in secondary education, social surveys of towns, with a view to the solution of community problems; business surveys for determining the commercial resources and trade possibilities of a community, visits to stores and firms "for the purpose of rendering individual assistance in meeting business problems" Quite distinct from the Extension Division is a "Summer Quarter" of ten weeks, in which are provided courses, some of post-graduate standard, in arts and pure sciences, engineering, medicine, and law. These, if pursued through the whole quarter, carry the same credit as similar courses in any other quarter.

Calendar of Industrial Pioneers.

September 24, 1852. John Barnes died.—From 1822 to 1835 Barnes was a partner with Joseph Miller, the marine engineer, and as such assisted in introducing steam navigation on the Rhône and Saône. He afterwards designed engines for vessels built by Normand of Havre, among these being the *Napoléon*, the first screw ship in the French Navy. At the time of his death he was manager of works at La Ciotat near Marseilles.

September 24, 1908. Sir Samuel Canning died.—Born in Wiltshire in 1823, Canning, after some years of railway engineering, joined the firm of Küper and Co., cable makers, of Greenwich, in 1852, and from that time onwards was intimately associated with the development of submarine telegraphy. He took part in the attempt to lay the Atlantic Cable in 1857 and 1858, and as chief engineer of the Telegraph Construction and Maintenance Company he had charge of the making and laying of the second and third Atlantic cables of 1865 and 1866. He was responsible for fitting out the *Great Eastern* and originated much of the cable machinery.

September 25, 1910. Edward Pritchard Martin died.—President of the Iron and Steel Institute and of the Institution of Mechanical Engineers, Martin was a metallurgist who, while manager of the Blaenavon Iron Works, was the first to give facilities for trying on a commercial scale the Thomas-Gilchrist process of dephosphorisation in steel-making. Martin was the son of a mining engineer of the Dowlais Iron Works, and was himself manager of those works from 1882 to 1902.

September 29, 1913. Rudolph Diesel died.—Diesel was born in Paris of German parents on March 15, 1858. He attended school in Augsburg, and at an early age became an assistant to Linde and directed works in Paris where Linde's refrigerators were constructed. Attacking the problem of making a prime mover of higher efficiency than hitherto existed, in 1893 he published "The Theory and Construction of a Rational Heat Motor," and the same year built his first experimental engine. After further trials the manufacture of Diesel engines was taken up by various firms, and to-day they are found in every part of the world. Their superior economy has led to their being fitted in ships, the s.s. *Toiler*, driven by two Diesel engines, crossed the Atlantic in 1911, while to-day more than 1600 vessels of a total tonnage of 1,500,000 tons are driven by internal combustion engines mainly of the Diesel type.

September 30, 1719. Bernard Renau d'Eliçagaray died.—The author of a treatise "Théorie de la manœuvre des vaisseaux," published in 1689, Renau d'Eliçagaray, as a naval officer, saw service afloat and ashore, and at Brest introduced new methods of shipbuilding. He took a leading part in the development of the French Navy under Louis XIV.

September 30, 1772. James Brindley died.—A native of Derbyshire, where he was born in 1716, Brindley served an apprenticeship to a millwright, and afterwards in business in Staffordshire for himself gained a reputation for his ingenuity and skill. For the Duke of Bridgewater he constructed the first British canal, that from Worsley to Manchester. This was completed in 1761, but before Brindley died he had built 365 miles of canal, including the Grand Trunk Canal from the Trent to the Mersey, thus laying the foundation of the British system of inland navigation.

Societies and Academies.

PARIS.

Academy of Sciences, August 21.—M. Emile Roux in the chair.—Paul **Vuillemin**: Disjunction and combination of the characters of the parents in a hybrid. Study of a hybrid of *Aquilegia cærulea* and *A. chrysantha*.—N. **Lusin** and W. **Sierpinski**: The decomposition of the continued fraction.—H. **Mineur**: A class of uniform transcendentals.—H. A. **Perkins**: The resistance of thin electrified conducting layers. Experimental study of the effect of an electrostatic charge on the resistance of thin gold film. The film formed one plate of a condenser, and no change in the resistance could be measured with or without an electrostatic charge of 2·7 C.G.S. electrostatic units (800 volts).—F. W. **Klingstedt**: The ultra-violet absorption spectra of the diphenols. A quantitative study of the normal absorption spectra of the dihydroxybenzenes, made with the Fabry and Buisson microphotometer on photographs taken by V. Henri's method. The meta- and ortho-derivatives have spectra very like that of phenol, but the para-compound has eight nearly equidistant bands instead of the three of phenol. The spectra are modified by certain solvents: with alcohol as a solvent it is impossible to recognise the characteristic differences between the para-compound and ortho- and meta-derivatives. Hexane is the best solvent.—H. **Gault** and R. **Guillemet**: The chlorination of normal butyl alcohol. The chief product was found to be the dibutyl acetal of dichlorobutyraldehyde, $C_4H_6Cl_2(O . CH_2 . CH_2 . CH_2 . CH_3)$. This acetal is not hydrolysed by aqueous potash, and only slightly hydrolysed by hydrochloric acid or dilute sulphuric acid at 150° under pressure.—G. **Vavon** and A. L. **Berton**: The borneol obtained starting with the magnesium compound of pinene chlorhydrate.—G. **Murgoci**: The properties of the blue amphiboles.—Marcel **Mirande**: The morphological origin of the internal liber of the Nolanaceæ and the systematic position of this family. The Nolanaceæ have been placed as allied with the Convolvulaceæ or the Solanaceæ: it is shown that this family is well differentiated from the Convolvulaceæ, but may be classified with the Solanaceæ.—A. **Guilliermond**: Cytological observation on a Leptomitus and in particular on the mode of formation and germination of the zoospores.—Georges **Bouvrain**: The vascular evolution in Mercurialis.—W. J. **Vernadsky**: Nickel and cobalt in the biosphere. The constant presence of nickel and cobalt in living organisms has not been proved; but they have been found in all cases when specially sought. They have been found in all the mosses studied in the neighbourhood of Kieff, and in nine species of plants from the same district. Cobalt has also been found in *Echium vulgare* from the Crimea, and in the ashes of a domestic mouse.—Louis **Boutan**: A fine culture pearl without nucleus.

The Protection of Inventions: An Empire Patent.

COMMON legislative action among the constituent parts of the British Empire would materially strengthen the bond which unites the peoples to one another and to the motherland. When, in addition, increased productiveness, lessening of cost, and simplification of procedure are its accompaniment, and when general expediency points to the special course prescribed by it, few voices could well be heard in opposition. For many years a dream of politicians and reformers, manufacturers and inventors, has been the granting of a single patent to an inventor which, effective throughout the British Dominions, would give adequate protection without the necessity of securing patents from each of the constituent countries of the Empire. To obtain this wide measure of protection, an inventor, at the present time, must make not less than forty-six separate applications at a cost in official fees of more than three hundred pounds Further, if protection be desired for the full periods which the respective laws permit, an additional sum of twelve hundred pounds and more must be forthcoming; and to this sum there is to be added the cost of the highly skilled preparation of the necessary documents, a formidable item which alone may amount to as much as the official fees for the applications. Now, if it were genuinely believed by all classes that the stimulation of invention results in greatly increased production, and that trouble and outlay in that direction are amply repaid, expenditure by governing bodies would no longer be deemed speculative, but would be looked upon as a sure and certain investment to be welcomed on all hands.

Although there is much to be urged in favour of this belief, possibly to the point of conviction, many reasons may be adduced for its non-acceptance by the authorities. The reasons, however, need not be specified, for the fact remains that hitherto there has been no such consensus of opinion as to lead the separate law-making bodies to common action and, through simplification of procedure and great reduction in cost, to encourage the inventor to successful effort within the territories of the several legislatures. Yet until the year 1852 it was the practice in this country to issue a single patent which was co-extensive in its operation with the whole of the Colonies, and in the Patent Law Amendment Act of that year a similar power was reserved. Although this power was not employed, for, in fact, no extensions were made, the reservation in the Act secured a practical result. It set on foot a series of inquiries by the Government, and led India and the Colonies to pass various patent

acts and ordinances. Simultaneously with the demand in the 'sixties of last century for the total abolition of patents, opinion was hardening upon the desirability for the extension of a patent to countries other than that in which it originated. In the Patents Act of 1883, which replaced the Act of 1852, no power was given for extending the territorial limit of a patent, nor in the Acts which now govern patents in this country is any such power present. In spite of much sporadic agitation, no practical steps were taken for a patent of the United Kingdom to become operative in India, the self-governing Dominions, the Colonies, and Protectorates. This invoked Sir Robert Hadfield to say that "It is a crying shame that in a great Empire like ours we do not have one Empire Patent to cover the whole of our Dominions."

Although many societies and various learned bodies had discussed the question and emphasised the need of an Empire Patent, and, from time to time, had made representations to Government, officialdom appears to have been deterred by inherent difficulties in the production of an acceptable scheme. It had not perceived the possibility of formulating a practical measure to satisfy the justifiable aspirations and fair demands of inventors. But steady pressure and persistent endeavour are meeting with reward, for there are now indications of Governments treating seriously the proposals for an Empire Patent. A notably important advance was made in 1921 at a conference of Prime Ministers and representatives of the United Kingdom, the Dominions, and India, when a memorandum, prepared in the Board of Trade, was discussed by a special committee. The conference agreed with the recommendation of its committee that representatives of the Patent Offices of His Majesty's Dominions should sit in London to consider the practicability of an Empire Patent. Accordingly sittings were held in June last, and a report of the conference has since been published.[1]

The report is not for popular reading; indeed in the main it is highly technical, and in its entirety can be understood only by those to whom the details of patent law and practice are of everyday concern. Further, its importance and significance are not to be measured simply by what it states expressly, since its implications and inferences must be gathered before its true import can be realised.

The discussion at the conference ranged round the present situation of affairs; the desirability for an Empire Patent; various schemes for obtaining the Patent and their practicability; and alternatively the possibility of rendering uniform the patent laws throughout the Empire. The conference, while emphasising the importance of the preservation of the autonomy of the self-governing Dominions and of India, and insisting upon the rights and facilities at present enjoyed by inventors, concluded that an Empire Patent is desirable. Five schemes of the many that had been brought to notice were selected for special examination, the conference taking for its basis a memorandum prepared by the Comptroller General of Patents in 1919. A few particulars of these schemes are set out in the report. Looking over these, it is apparent that for each much can be urged. In one, it may be, large expenditure is involved, although the advantages to be secured are great; in another, expenditure is comparatively small, with corresponding diminution in beneficial results. That difficulties will be encountered whatever scheme may ultimately be adopted is well known, but so far as can be judged, no such difficulty will be met as cannot be surmounted in the presence of a spirit of give-and-take, a spirit which must permeate the various legislatures and governing bodies before a uniform plan of action can be agreed upon.

According to one of the schemes, there is to be established a single central patent office for the issue of grants which should be operative throughout the Empire, local patent offices being abolished. This scheme was not approved, "having regard to practical difficulties," the chief of which were the distance apart of the units of the Empire and the loss of time which accordingly would be involved in transacting the necessary business. Another scheme contemplated the retention of local patent offices from which the usual territorial patents would issue, the issue taking place without examination into the novelty of the inventions to be protected. In addition a central office would be established for the recording of the local patents and for their resultant extension to the Empire. The central office on being called upon by its patentees would also undertake a limited examination for novelty, and when the patent specification was suitably amended as a result of the examination, a note would appear that the examination had thus taken place. This scheme was not recommended, owing, it would seem, to the resulting abolition of the existing compulsory examination into novelty. The third scheme entailed the granting of Empire Patents in each self-governing Dominion and in India, each office being fully equipped with the registers and material necessary for the examination into novelty. In view of the expense and difficulty involved in setting up the offices and of the uncertainty as to the quality and value of the patent so granted, the conference found the scheme to be wholly impracticable. According to the "Preferred

[1] British Empire Patent Conference. Report of the Conference held at the Patent Office, London, from 12th June 1922 to the 23rd June 1922. 8vo. Pp. [illegible]. (London: H.M. Stationery Office.) 1s. net.

Scheme," a scheme which the conference recommended for adoption in the future, local patent offices are to be retained, each performing its present functions. There is also to be a fully organised central office for the detailed examination of applications for patents, the examination to include an extended search for novelty, the office eventually issuing the Empire Patents. But to make a patent operative in any country, registration in that country is compulsory, the registration being open to opposition if the local law provides for opposition to the granting of a patent.

By a "Provisional Scheme," which is recommended for immediate adoption and for continuation until the "Preferred Scheme" can be introduced, the grant of a patent in the United Kingdom carries with it the right to registration in any desired country of the Empire, the act of registration extending the grant to that country. But here, again, before the registration is made, it is open to opposition, if opposition to local grants is permitted by the local law.

Manifestly, whatever scheme came to be adopted by the separate legislatures or law-making bodies, much mutual adjustment of substantive and adjective law would be required. Some of these necessary adjustments were discussed at the conference, and suggestions emanating therefrom appear in the report. None appears to be of such a character as to be outside the bounds of practicability. But to review those subjects which call for adjustment, and to discuss the opinions on these and other points expressed at the conference, would require for each a monograph. From the report it is clear that an extremely small portion of the necessary amendments which the respective authorities would be called upon to make could have been discussed, bearing in mind that the conference held ten meetings only, and that it refused to admit oral evidence from outside, deciding that "no useful purpose would be served by hearing such evidence." There was, therefore, excluded from consideration the oral evidence that could have been given, for example, by the Chartered Institute of Patent Agents, a body which is continually in touch with the needs of inventors and conversant with the working and details of the various patent laws. Of necessity must the conference be looked upon as merely preliminary to attacking at close quarters the problem which it set out to solve.

On the unanimous selection of a scheme by each of the governing authorities, the next step will be for each to submit for general consideration the law, rules, and regulations which must be formulated in order that the selected scheme may be successfully put into operation. Moreover, it will be necessary to distinguish between the law to be applied when the patent is granted and the procedure for obtaining the patent. It will also be found that, in endeavouring to secure a basis for action, the task will be the easier by reason of the large majority of the patent laws of the Dominions having copied the law of the United Kingdom, and of the ultimate Court of Appeal for the Empire being the Judicial Committee of the Privy Council.

In the preparation of a scheme for general adoption it is to be hoped that the authorities will not continue to ignore oral evidence from outside bodies; to do so will be to court failure. Procedure for obtaining a patent and the law and rules relating to patents are so intricate that none but those who are in daily contact with such matters and have learned in the hard school of experience the needs of inventors on one hand and the reasonable requirements of the public on the other, can be expected to produce a scheme which, satisfactory to all parties, can be put into operation without friction, much change in procedure, or extensive amendment of existing laws.

There is no reason to suppose that, if all parties are determined to produce an Empire Patent, the adjustment of conflicting opinions cannot be made nor suitable machinery devised. The result undoubtedly would be to the advantage of all inhabitants of the Homeland and of His Majesty's Dominions beyond the Seas, whether as inventors, manufacturers, or users. It remains, therefore, for the public to urge expedition upon the authorities, or it will be met with the charge of apathy, a plea which so often saves the situation where officials are concerned.

A word or two is to be said in respect of the charge for a copy of the report. In pre-war days, each copy of this small octavo would have been sold for *3d.* or *4d.*, and the edition promptly exhausted with a consequent wide-spread dissemination of its information. For each copy of this edition of five hundred, however, one shilling is required, a charge which scarcely makes for extensive circulation. The wider the public that the report reaches, the greater chance of a definite outcome of its suggestions, while, at the same time, by the lowering of the price the probability of the recovery of the cost of the edition would not be appreciably lessened.

Industrial Physics.

A Dictionary of Applied Physics. Edited by Sir Richard Glazebrook. (In 5 volumes.) Vol. 1: Mechanics, Engineering, Heat. Pp. ix + 1067. (London: Macmillan and Co., Ltd., 1922.) *3l. 3s.* net.

IN years to come the publication of this monumental work will rank as one of the milestones in British applied science. If argument were needed, none more

convincing could be adduced in illustration of the necessity for a working co-operation between the physicist and the engineer. Sir Alfred Ewing recently defined engineering as "the turning to man's use and convenience of the things which it is the business of physics to understand." This Dictionary helps one to realise, as perhaps never previously, that in all branches of engineering the engineer, whether revealing or directing, whether inventing or designing, whether testing or measuring, whether systematising, co-ordinating, or clarifying, is continually turning physical principles to account.

Sir Richard Glazebrook, not content with the enduring monument to his fame in the shape of the National Physical Laboratory, has now laid physicists and engineers under perpetual obligation by undertaking the editorship of this "Dictionary of Applied Physics." No other British man of science, it is safe to say, could have brought the same wide experience, intimate knowledge, and critical judgment to bear upon the production of an encyclopædic work of this nature. For twenty years Sir Richard Glazebrook directed the policy of the N.P.L., and during that period, when the attitude of the nation towards scientific investigation was very different from what it is to-day, he toiled unceasingly to foster the applications of science to industry. To take one example alone, the fact that this country in 1914 led the world in aeronautical research is due in no small measure to his foresight and skilful guidance during the preceding eight years. Sir Richard's breadth of interests and his habit of establishing and preserving personal contact with original investigators are reflected in his choice of collaborators in the preparation of this Dictionary.

The work under review is the first of a series of five volumes, planned to cover the entire range of physics and, in particular, the applications of physics to industry. Volume 1 contains some fifty articles, covering mechanics, engineering, and heat.

Three main facts emerge from a survey of the work before us—first, the unexampled wealth of material; secondly, the authoritativeness, the maturity of judgment, the originality and inviting freshness of treatment which are exhibited by the majority of the writers; and, lastly, the presumption and futility of any single reviewer attempting to appraise such a diversity of articles by such a galaxy of experts. A glance at the names of contributors furnishes sufficient guarantee that the various subjects are dealt with by accepted authorities and experienced investigators; and probably the most useful service that a reviewer can hope to perform is to point out a few of the sins of omission which are inevitable in a treatise planned on such a comprehensive scale.

The first article in the volume is on air pumps, by the staff of the General Electric Co., and deals with the fundamental principles of the various types of pumps employed for evacuation and compression.

Calorimetric measurements are dealt with in a series of five articles by Dr. Ezer Griffiths. The subject is divided into sections dealing with bomb calorimetry, electrical methods of calorimetry, method of mixtures, methods based on change of state and the applications of the quantum theory to specific heat data. A glance through these articles shows how different are the methods employed by research workers from those described in text-books on this subject. As an indication of the highly developed state of technical calorimetry, it might be mentioned that with one of the bomb-calorimeter equipments described—that of the U.S. Bureau of Mines—a skilled operator can average thirty-five determinations per day of the calorific value of fuels. The purely scientific aspect of the subject is not neglected, for we find concise descriptions of the researches of White on specific heats at high temperatures and those of Dewar at low temperatures. Electrical methods of calorimetry naturally occupy a prominent place, for the ease with which electrical energy can be measured and controlled has placed a powerful tool in the hands of workers concerned with thermal measurements.

The principles of dynamical similarity are discussed in an article by Dr. H. Levy. The results of wind-channel and ship-tank experiments on models can be applied to full-scale machines by the use of the Principle of Similitude, which also finds application in numerous other branches of engineering. One is reminded of a famous article by the late Lord Rayleigh in NATURE, vol. 95, p. 66, 1915, in which the full generality and beauty of the Principle of Similitude are brought out. In the space of a column or two Rayleigh deduced a series of fundamental conclusions with the lucidity and brevity which distinguish all his writings.

Four articles are devoted to various aspects of steam engineering. Sir Alfred Ewing contributes one on the theory of the steam engine; Mr. A. Cruickshank another on the reciprocating steam engine, while the importance of the steam turbine fully merits the 38 pages devoted to the two articles on the physics of the steam turbine by Dr. Gerald Stoney and Mr. Telford Petrie, and the development of the steam turbine by Mr. R. Dowson of Messrs. Parsons.

These articles cover the ground pretty thoroughly, so far as present-day practice goes, but one would have liked to know something of the writers' views on the future trend of their subjects. For example, nothing is said of the possibilities of the gas turbine, should the practical difficulties connected with it be overcome, or

of the advantages and disadvantages of the steam turbine for aircraft propulsion and on locomotives.

The internal combustion engine is dealt with in three articles: Mr. Aubrey Evans writes on the water-cooled petrol engine; Sir Dugald Clerk and Mr. G. A. Burls on the thermodynamics of internal combustion engines and also on some typical internal combustion engines. The standard work of these authors on the subject is familiar to most students.

On general engineering subjects we note, among many others, a brief monograph by Prof. W. E. Dalby on the balancing of engines and prime movers. In an article on the strength of structures by Mr. J. W. Landon, it is curious that no mention is made of airship and aeroplane structures, which are certainly of considerable interest at the present time.

Dr. T. E. Stanton's article on friction, supplemented by a very brief one by Mr. W. B. Hardy on boundary conditions in lubrication, form a complete and masterly résumé of this fascinating subject, in which there have been considerable developments during the past few years.

Elasticity has two articles devoted to it, one on the theory of elasticity by Mr. R. V. Southwell, and the other on elastic constants by Mr. R. G. Batson. Mr. Southwell's article of 11 pages is as brief as Mr. Batson's article of 125 pages is long. One would have liked to see included in the former a brief account of the mathematical researches which find practical application, such as the effect of keyways on the strength of a shaft, the vibration of rotating masses, such as turbine discs, the torsional vibration of propeller shafts, etc. Mr. Batson's article, which is lavishly illustrated, deals primarily with the testing of the materials of construction. We note that Fig. 120, p. 196, has evidently been transferred direct from a catalogue without the superfluous lettering being removed. In view of the thorough treatment of the subject of thermoelectric pyrometry in this volume, there was doubtful justification for including an elementary account of the principle of thermoelectric pyrometers in an article devoted to elasticity. Moreover, the sections on the permeability of concrete, together with those on attrition and abrasion tests, are somewhat uncomfortably housed in an article on elastic constants. The question of the seasoning and testing of timber merits a more exhaustive treatment than is accorded to it here.

Space does not permit of a review of the numerous short articles on various aspects of engineering, but some of the omissions may be pointed out for future rectification. In the brief article on gyroscopes by Dr. G. T. Bennett, no mention is made of important practical applications, such as gyro-compasses, stabilisers, and aeroplane-level indicators. The article on dynamometers, by Mr. J. H. Hyde, is confined mainly to the more familiar types. One would have liked, for example, to know something of those developed for testing aircraft engines during flight.

Mr. F. H. Schofield contributes articles on heat conduction and convection, the recent work of the Heat Department of the National Physical Laboratory on these subjects being well summarised. The classical researches on the mechanical equivalent of heat are ably reviewed by Dr. E. H. Griffiths. Reading his account of the difficulties encountered by early workers makes us realise how much they did indirectly to advance progress by following up the discrepancies between various temperature scales on one hand and the several electrical standards on the other. Sir Alfred Ewing contributes articles on thermodynamics, the liquefaction of gases and refrigeration, which are models of charm and clarity. The article on liquefaction might well have been amplified to include the advances of the last few years.

Temperature measurements are covered in a series of six articles. Messrs. Day and Sosman of the Geophysical Institute, U.S.A., are authors of an article on the realisation of the absolute scale of temperature. In this most readable contribution will be found a critical review of the numerous researches on the gas thermometer throughout the past century, which have helped to lay the basis of the standard scale of temperature in use at the present day.

Dr. Ezer Griffiths contributes noteworthy articles on resistance thermometers, thermocouples, total radiation pyrometry, and optical pyrometry. The resistance thermometer holds a unique position in practical pyrometry. Too fragile for works' use, as originally intended by Siemens, it has developed into a precision laboratory instrument. The practical scale of temperature over the range −40° C. to +1100° C. can be reproduced with extraordinary accuracy by the aid of a platinum resistance thermometer calibrated at the ice, steam, and sulphur points. Detailed descriptions of the methods to be employed in calibration and the precautions which must be observed will be found in the article.

As modern methods of measuring temperature have developed chiefly in the direction of electrical appliances, one naturally finds that prominence is given to a discussion of various types of potentiometers in the article on thermocouples. Considerable advance has been made in recent years in the design of thermo-electric potentiometers, and the student of purely electrical measurements might also with advantage study this section.

A notable feature of the article on optical pyrometers is the discussion of the theory underlying the

use of red glass for obtaining approximately monochromatic light. This is a factor of fundamental importance when temperatures of the order of 3000° C. have to be measured by means of pyrometers calibrated on the basis of Wien's law to represent the distribution of energy in the spectrum of a "full radiator" The "disappearing filament" type of pyrometer has been greatly developed in recent years at the N.P.L. and elsewhere, and it would appear that, in time, it will supplant most of the other types now in use for high-temperature measurements.

Thermometry is covered by a comprehensive article written by Mr. W. F. Higgins. A detailed account is given of the N.P.L. equipment for thermometer testing, together with a complete discussion of the mercurial thermometer. No consideration is given to vapour-pressure thermometers. During the war many thousands per week were made for use on aircraft, and they are also being extensively fitted to motor-car radiators at the present time. Doubtless the new mercury-in-steel transmitting thermometers, which have been successfully developed and are coming into wide use, will receive a longer notice in a future edition.

Mr. G. S. Baker writes on ship resistance, Prof. Horace Lamb contributes mathematical articles on Fourier's series, etc., Dr. A. W. Porter treats of thermal conductivity, and Mr. Jakeman deals with the measurement of pressure.

We regret that we have not space to notice the numerous short articles scattered throughout the volume, some of which are intended to supplement the longer articles.

There is an excellent name-index. The references are plentiful, and appear to have been carefully checked. The only slip which we have noticed is on page 1025, the Physical Society modestly confining itself to Proceedings, not Transactions, as implied by the writer. We notice that the names of Mr. Whetham (Phase Rule) and Miss Austin (Units of Measurement) have been omitted from the list of contributors on p. vii.

The printers have done their work well, and the publishers are to be congratulated on their enterprise and the general "turn-out" of the book. It was inevitable that a book of 1000 or more pages of this type should be expensive. The pity of it is that the price will put it out of the reach of so many students. It is true that they may have recourse to the nearest library, but the book is such that one would like to see every senior student of the subject with his own copy. Some of the articles will be a revelation to him, bearing as they do little resemblance in substance and treatment to the majority of the present-day text-books.

The division of the Dictionary into volumes on a subject-basis, and the fact that individual volumes are purchasable, are features greatly to be commended. Perhaps in the future it may prove possible to extend the system and divide the Dictionary into, say, double the number of smaller volumes, each confined to one main branch of the subject, and proportionately less costly. The volumes would be lighter to handle, and the formidable task of keeping so large a work abreast of modern science would be much facilitated.

G. W. C. KAYE.

Position of Agriculture in India.

Agricultural Progress in Western India. By G. Keatinge. Pp. xii + 253. (London: Longmans, Green and Co., 1921.) 6*s*. net.

AGRICULTURAL conditions in India are such that any estimate of progress must be largely indirect. The bulk of the land is farmed in small holdings by peasants who keep no accounts, and sell their surplus products in local markets which render no statistical returns; again, the value of export crops, such as cotton, is subject to wide fluctuations owing to the erratic rainfall. But, by a consideration of other factors, such as the area under cultivation, changes in land values and rentals, irrigation schemes, and the standard of living, there is definite evidence of progress. Mr. Keatinge has spent thirty years in the midst of agricultural problems in the Bombay Presidency, and in this very interesting book he sets out his estimate of the progress that has been made, the obstacles to further advancement, and a proposed future policy.

With regard to the obstacles in the way of further advancement, the most serious one is the Hindu law of inheritance, by which each male member of a family is entitled to an equal share of the family property. This results, not only in the division of farms into uneconomic units, but in a further subdivision into scattered plots—a process reminiscent of the old three-field system in England. Another fundamental difficulty is that cattle cannot be bred and kept solely for profit, owing to their significance in the Hindu religion. They are of inefficient types, used of necessity in an uneconomic manner, and are more of a hindrance than a help to the struggling farmer. As an illustration of the difficulty of introducing improvements which do not clash seriously with the social and religious habits of the cultivators, the author considers the use of irrigation water. It appears that, financially, most irrigation canals are unsuccessful owing to the slow manner in which these facilities are

taken up. This is due to the small number of men who have the necessary capital, skill, and energy to engage in the more intensive type of cultivation necessary on irrigated land.

In certain matters of technique, such as improvements in cultivation and rotations, the application of manures and the use of better seed, considerable advances have been effected. This is largely due to the investigations made at the experimental farms of the Agricultural Service.

In one of the appendices to the book the author outlines a draft bill to enable landowners to correct the excessive division of holdings, and he supports his case by full details of typical instances of sub-division, and by comparison with the remedial measures taken in other countries where the same conditions have arisen.

The book is essentially a plea for a specified course of legislative action, and therefore may be to some extent controversial, especially at the present time; but the facts are put forward in an eminently fair manner, and the author's treatment and discussion of them constitute an exceedingly interesting and useful account of agricultural conditions in an important region of India.

B. A. KEEN.

Prehistory for the Schoolroom.

(1) *Everyday Life in the Old Stone Age.* Written and illustrated by M. and C. H. B. Quennell. (The Everyday Life Series, I.) Pp. x + 109. (London B. T. Batsford, Ltd., n.d.) 5*s*. net.

(2) *The World-Story of 3,000,000,000 (?) Years* By J. Reeves Pp. 16. (London: P. S King and Son, Ltd 1922.) 2*s* 6*d*. net.

(1) THIS is a delightful book It ought to be in every schoolroom, but the elders will want to borrow it and enjoy it in the evenings The line drawings are masterpieces of well directed imagination. That on p. 48 shows a Mousterian family between the thin stems of the woodland and their cave; the big brother, just for fun, is frightening a little girl, who clings to her mother's back as she looks after the fire; an elder sister, sitting near him, checks him by a timely touch from her leg—her foot is just as ready as her hand. The 130 square cm. of the drawing—the authors justly use the metric scale—are full of life and incident; we should like to see the curtain rising on its realisation as the first scene of a folk-drama.

The clever guesses at the appearance in profile of successive types of man, from Pithecanthropus to the Magdalenian, should be supplemented by a few drawings of the actual skulls. There is no ugly suggestion nowadays about a skull, and readers would then see clearly on what the conclusions rest. The picture of a small valley-glacier producing a moraine-girdle is crude, and does little to explain the conditions found by earliest man in Europe. The absurdly small thickness assigned to Cainozoic strata in the table is sanctioned by British Museum guides, and is derived from the narrow cult of the London Basin by geologists in southern England But we turn to the text and the living illustrations, to the proud dignity of *Cervus giganteus*, unconscious of his vulgar little enemy in the rear, and to the sleepy hippopotamus about to fall upon the stakes; then once more we cordially thank the authors.

(2) So much is problematic when we seek to summarise "the world-story" that we doubt the wisdom of drawing up charts which simulate those derived from written history. Mr. Reeves's book is, however, very useful to the teacher; but it necessarily contains much on which we await further information. By reserving the theromorphs, for example, for the Trias, the author is able to state that the Permian reptiles were not at first clearly differentiated from amphibians. The marvel, however, lies in the rapid rise in Permian times of a mammalo-reptilian type. The hypotheses of the earth's origin do not fit well with tables showing in detail the "periods" of man's occupation of the globe. We have the "solar planetary epoch," the Carboniferous "period," and later the La Tène "period" Unless the geological section is greatly extended, undue emphasis is thrown on the analysis by archæologists of the progress of early man in the European area. Prof. Sollas's estimates, made in 1909, are wisely taken as a basis for suggesting, by thickness of strata, the relative lengths of geological periods. The author's references to literature should aid the schoolmaster who attempts to deal with man as "a part of Nature" But how are other forms of teaching, in Kentucky, in Middlesex, and elsewhere, to be reconciled with this high ideal?

G A J. C.

Aesthetics.

(1) *Harmonism and Conscious Evolution* By Sir Charles Walston (Waldstein). Pp. xvi + 463. (London: J. Murray, 1922.) 21*s*. net

(2) *The Poetic Mind.* By F. C. Prescott. Pp. xx + 308. (New York: The Macmillan Co., London: Macmillan and Co. Ltd., 1922.) 9*s*. net.

(1) HARMONISM, whatever its attraction as a theory, has chosen very unharmonious terms for its expression. Sir Charles Walston's theory is, in his own words, that conscious evolution in the

human being is due to harmoniotropism rising in its higher stages to aristotropism. "The new born infant," we are told, "emits a first sound or cry which is a spontaneous activity of its vocal chords. From this moment numerous somatocentric and centrobaric activities proceed which—unconsciously to the infant itself—establish its relationship to its own functioning body and to the outer world. But with the growth of sentience and nervous activity all the physiological activities of the child are somatocentric, and manifest geometrical or rhythmical regularity, establishing the harmoniotropic tendency and principle of activity."

The book contains a great amount of autobiography and many long extracts from the author's other writings. So far as æsthetics is concerned Sir Charles seems to come nearest to Groos's play theory. He makes no mention of the more recent æsthetic theories, that of Benedetto Croce for example. Art, we are told, is the product of an æsthetic instinct, and we seem to be expected to find the full explanation of it in this description. The purpose of the book is practical, however, rather than theoretical. The idea that inspires the whole scheme is the desire to find a way to reap the full benefit of the awful experience of war and direct to good purpose the agencies, such as the League of Nations, which aim at superseding the conditions which are making strife on the colossal scale a menace to civilisation.

(2) Mr. Prescott's book is a research work in connexion with, or at least undertaken at, Cornell University. It is a laborious attempt to prove a thesis by accumulating examples and illustrations. The thesis is that poetry is a product of the human mind which is to be correlated with dream consciousness. We are thinkers and dreamers. Most of us are both, but in a general way we may class people as one or the other according as imagination or reasoning is their predominant mental activity. It was therefore even more to M. Jourdain's credit than he supposed that he should have been speaking prose all his life. Mr. Prescott is a disciple of Freud and Jung and his thesis is that the dream interpretation of those psychologists is applicable, not merely in general, but in minute detail, to the interpretation of the imaginative content of poetry. It is a thesis which bears very hardly on the poets, and if it is right, they, being dreamers and not thinkers, will find it difficult to put in a defence. Our quarrel, however, is not with his psychology but with his inadequate conception of æsthetics. Poetry is indeed, as Vico was the first to hold, the primitive language, but surely when dreams find expression in poetry they cease to be dreams.

Both these volumes seem to illustrate the impossibility of treating æsthetic subjects without coming to a clear decision first as to what precisely the æsthetic function is, and second, as to what is the exact relation in which it stands to the logical function. It is no use short-circuiting the inquiry by dismissing æsthetic activity as an instinct, or by degrading it to descriptive psychology. Moreover, the work of Benedetto Croce in this field, open to criticism as it may be, has left research students with no excuse for ignoring the issue. Notwithstanding this defect, each of these books is, in its own way, fresh and original and distinctly stimulating to thought.

Our Bookshelf.

A Naturalist in the Great Lakes Region. By Elliot Rowland Downing. (The University of Chicago Nature-Study Series.) Pp. xxv+328. (Chicago, Ill.: University of Chicago Press, 1922.) 3.50 dollars.

THIS book has been written by a member of the School of Education at Chicago University as one of its nature-study series of handbooks, and it is designed for teachers of nature-study as a guide to the ecology of the country bordering Lake Michigan in the vicinity of Chicago. It is written on ecological lines, and shows abundant evidence of the influence of the American school of ecologists headed by Dr. C. G. Adams and Dr. V. E. Shelford. An account of the geology of the district is given first, followed by a résumé of the geological changes which have led to the present conformation of the country, with special reference to the glacial period and the formation of the basins of the Great Lakes. The animal and plant associations of the district are then dealt with in some detail under the headings: dune, forest, swamp, prairie, and the various aquatic types.

The book is abundantly illustrated by line drawings, which will serve at any rate for a preliminary identification of the animals and plants met with, and a very good series of photographs illustrating the various geological phenomena and biological associations which are described in the text. Many of the maps, however, are too small and so overloaded by unnecessary detail as to render obscure the point they are designed to illustrate. The book will serve admirably the purpose for which it is designed, and should be of the greatest use to teachers and students of Nature in the area with which it deals.

It is evident, however, that the author is not himself familiar with the scientific names of the animals and plants of which he writes. There are dozens of mistakes in the spelling of these names, and if a second edition is called for, the author would do well to enlist the services of a competent zoologist and botanist and submit his scientific names to them for correction. The index, too, shows evidence of hasty compilation. It is neither complete nor accurate. These defects are a serious blot on an otherwise useful book, and should be remedied as soon as possible. Fig. 56, too, might usefully be replaced by a series of new and more accurate figures.

Department of Scientific and Industrial Research. Bulletin No. 6. On the Electro-Deposition of Iron: With an Appendix containing a bibliography of the subject. By W. E. Hughes. Pp. iv + 50. (London: H.M. Stationery Office, 1922.) 6*s*. 6*d*. net.

THE Department of Scientific and Industrial Research has rendered electrometallurgists signal service by the recent publication of this monograph, written by and containing the results of work by Mr. W. E. Hughes, formerly Chief Research Chemist to the Electrometallurgical Committee of the Ministry of Munitions, and already favourably known for his publications in this particular field. The present brochure contains, within the compass of fifty pages, a systematic study of the effect of current density, temperature, and mechanical movement on the nature of the cathodic deposit of iron formed from ferrous chloride solutions. The deposits were photomicrographed in every case, and the resulting numerous illustrations, excellently reproduced, are of considerable interest.

The view upheld by the author is that the effects of these different factors can all be satisfactorily explained if the formation of a crystalline cathodic metal deposit can be regarded as being governed by conditions similar to those which regulate the nature of a crystalline deposit formed from, say, a molten mass of metal, a fused rock magma, or an aqueous solution. It cannot be said that the view is quite novel. It has certainly been "in the air" for some little time. The striking work of von Weimarn, for example, if considered in connexion with the effect of colloidal additions to an electrolyte on the nature of the cathodic deposit, could not but suggest a close similarity between the nature of the phenomena of electrolytic deposition and precipitation from aqueous solutions. But to Mr. Hughes belongs the credit of stating the analogy in unequivocal language, and of bringing to it a very large measure of experimental support. The variations in crystal structure observed by him are correlated very satisfactorily with changes in the experimental conditions mentioned above, changes which bring about quite similar variations in the nature of crystallisation from other types of systems.

It should be added that an excellent bibliography of the subject is given in the form of an appendix.

Catalogue of the Fossil Bryozoa (Polyzoa) in the Department of Geology, British Museum (Natural History). The Cretaceous Bryozoa (Polyzoa). Vol. 4: The Cribrimorphs. Part 2. By Dr. W. D. Lang. Pp. 12 + 404 + 8 plates. (London: British Museum (Natural History), 1922.) 1*l*. 12*s*. 6*d*.

THOSE who use this volume will bear in mind the illuminating morphological introduction provided by the author in its predecessor (see NATURE, vol. 108, p. 39). The numerous lithographs are from the artistic drawings of Miss G. M. Woodward, and the author again furnishes vigorous text-illustrations showing the specific orthœcia (normal zoœcia) and the accompanying aviculœcia, which are the skeletons of the modified polypides that defend the colony. The variety of form, position, and number in the aviculœcia will surprise those who are not specialists. The general account of the genus Pelmatopora (pp. 241-253) is a good example of Dr. Lang's attractive method of dealing with Nature's species-making, here styled "evolutionary activity." In this case the whole of the thirty-eight species are derived from zones in the Senonian.

G. A. J. C.

Pope's Manual of Nursing Procedure. By Amy E. Pope. Pp. xi + 596. (New York and London: G. P. Putnam's Sons, 1919.) Price 15*s*.

THIS book has been prepared more especially to facilitate practical instruction in the work usually included in the probationer's first year of training. In each section a consideration of the principles underlying the various nursing procedures is followed by a description of demonstrations of the methods involved. In this way, and with frequent reference to physiology, the author associates theory with practice.

There are a few errors and omissions; in the description of Fowler's position, a right angle is represented diagrammatically and in the text as 100°; and in the list of prescription abbreviations and symbols no mention is made of the commonest in use, that for "thrice daily." The use of more illustrations would enable a reduction to be made in the length of descriptions of technique. The book is more suitable for the guidance of the instructor than as a manual for the probationer.

Précis d'Arithmétique. Par J. Poirée. Pp. x + 63. (Paris: Gauthier-Villars et Cie, 1921.) 7.50 francs.

M. POIRÉE has not written a book on arithmetic in the sense of a school text-book: it can be more accurately described as an introduction to the theory of arithmetic. Although the author sets out with care and precision the main ideas underlying arithmetical processes—"the why and the mechanism of each operation"—yet there is no attempt made to teach the subject. The book is very interesting—is there a French book on mathematics that does not make pleasant reading? A quarter of the space is devoted to the fundamental theorems of the theory of numbers, and in fact all through the book there is an evident suggestion that the author is aiming at the theory of numbers. Numerical illustrations of the processes are given, but there are no exercises for the student to work out himself.

S. B.

Practical Physics. By W. R. Bower and Prof. J. Satterly. Eighth impression (second edition). Pp. xi + 422. (London: University Tutorial Press, Ltd., 1922.) 7*s*.

A DISTINCTIVE feature of this text-book of practical physics is the inclusion of a considerable number of experiments which may be performed by the student at home, using very simple apparatus. In the second edition a supplement has been added containing a number of additional experiments. These are concerned with Fletcher's trolley apparatus, coefficients of friction, Mariotte's bottle, surface tension, expansion of solids, thermal conductivity, photometers, and critical angles. The importance of avoiding eye-strain has not been sufficiently considered in the mathematical tables at the end of the volume.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Relativity and the Æther.

WHILE at Brighton recently I visited its excellent Public Library, and there found the three supplementary volumes of the "Ency. Brit." containing the remarkably lucid article on relativity by Dr. Jeans. Many have written and multitudes have read about this subject, but I venture to say that nowhere can be found a more compact and accurate presentation of the strict relativist position. There is nothing anæmic or half-hearted about it; and I imagine that while non-physicists will find the article readable, most physicists will find its crisp clearness instructive. Very little can a pragmatic or anti-philosophic relativist like myself find to disagree with in it, and where I do disagree it is just possible that both or neither may be right.

Still I do want to quote and criticise one clear and definite sentence, into which I insert only references to my comments which follow, so as not to spoil it.

On the electromagnetic theory of Faraday and Maxwell, waves of light "were simply waves in the æther and travelled with an absolute velocity c determined once and for all by the structure of the æther. (1) On this view it was quite certain (2) that an observer moving through the æther with a velocity u would measure the velocity of light travelling in the same direction as himself as $c-u$. Relativity teaches (3) that this velocity is always precisely c, and this in itself disposes (4) of the æther of Faraday and Maxwell."

On this pronouncement I comment thus:—

(1) That is certainly true.

(2) Not *quite* certain. It might have been thought certain; but the FitzGerald contraction is an indication of unexpected possibilities in the instruments of measure. Still, no first order loophole has been suggested, and the challenge is a legitimate one. Would that the experiment could be tried![1] I assume that every one will agree that it has not yet been tried, and that it is difficult to devise a sure and certain way.

(3) It certainly and very forcibly does so teach.

(4) But a hypothesis, even the foundation hypothesis of a developed theory, cannot logically be cited as if it were an experimentally ascertained and conclusive fact; nor can it be used to give a knock-out blow to another theory. Opposing theories still have to fight it out. Full-blown Relativity might equally well be said to dispose of Matter, by reducing it to the unevenness of a field, or to the tensor $-8\pi T_{\mu\nu}$, or to an algebraic expression like $G_{\mu\nu}-\frac{1}{2}g_{\mu\nu}G$, which apparently is conserved like matter, is obedient to our laws of motion, and vanishes in what we call empty space.

I do not think that even Dr. Jeans will claim that there is any ascertained fact to substantiate what I have marked as (3). It all depends upon uv/c^2 and differing estimates of time.

It may be said that conclusions of relativity have been verified, and that thus the theory is established. I should prefer to say that some mathematical deductions arrived at by the relativity method have been brilliantly verified, and hence that the method has pragmatically been proved to be sound. I should not say that its philosophic foundations were established; still less that they have rendered all other foundations rotten.

It would seem rather that more than one mode of expression is possible for even the simplest fact, and that a criterion of absolute and exclusive truth in any statement is increasingly difficult to find. A theory which renders it uncertain whether the Fire of London preceded or succeeded the outburst of Nova Persei, whether the sun revolves round the earth or *vice versa*, and whether a much-travelled man's death preceded his birth, should not be too positive when it leaves its own realm and enters the region of fact and reality, whatever those possibly question-begging terms may mean. Perhaps there is no absolute truth. More probably absolute truth exists, but is not easy to arrive at.

Meanwhile we may be grateful that, thanks to the new school, we are beginning to recognise the uncertainty and contingency inseparable from all forms of human statement. Let our geniuses not extinguish but supplement each other. There is room not only for Einstein and Weyl but also for Newton and Maxwell. The reconciliation may not be obvious, the connecting passage is difficult to find, but it would be wise to keep the door ajar.

OLIVER LODGE.

The Legal Equivalent of the Metre.

MAY I correct in NATURE an unfortunate error which occurs on p. 580 of the "Dictionary of Applied Physics"? It is there stated that the equivalent of the metre in inches is 39·37008, and the Order in Council of May 19, 1898, is referred to as giving the legalised value of this quantity. The information was taken, by permission, from the "Computer's Handbook," issued by the Meteorological Office in 1921, and the inference is that the above figure is the legalised value.

Dr. Stratton, of the United States Bureau of Standards, recently directed my attention to the error. The legalised value given in the Order of Council is 39·370113 inches.

The "Computer's Handbook" states that: "The most recent values for the metrical equivalent of the fundamental British Units are those contained in the Order of Council of 19th May 1898," and, after a reference to earlier editions of the "Handbook," continues: "Values in accordance with the Order in Council of 1898 have now been substituted."

I assumed this to mean that the actual legalised values had been used and printed the figures without further verification, but this is not the case.

The figure given—39·37008—is deduced from the relation 1 inch = 25·4 millimetres; the legalised value of the inch in millimetres is 25·399978. The difference, less than one part in a million, is negligible for nearly all purposes and there would be many advantages in accepting, as the legalised ratio, 1 inch = 25·4 millimetres, but this has not been done.

At present some confusion may easily arise; for in America the ratio 1 metre = 39·370000 inches has been adopted.

We thus have the equivalents given in the following table:

	Metre in Inches.	Inches in Millimetres.
America	39·370000	25·400051
"Computer's Handbook" .	39·37008	25·40000
British Legalised Value . .	39·370113	25·399978

The matter is discussed in an article on metrology by Mr. Sears, which will appear in the forthcoming volume of the "Dictionary of Applied Physics."

R. T. Glazebrook.

Coton End, 63 Grange Road, Cambridge,
September 9.

On the Reality of Nerve-Energy.

If I have understood Prof. Fraser Harris's letter in Nature of September 9, p. 342, it is a plea for the more widespread use of the term "nerve-energy" by physiologists and for the investigation of it as a special manifestation of energy like heat, light, or electricity. It is no doubt quite true that the term has a definite and useful meaning in psychology and psycho-pathology, though "mental energy" would probably do as well in most cases.

As a physiological concept, however, "nerve-energy" has little to recommend it. Some idea of the difficulties which are likely to attend its use may be seen even in Prof. Harris's letter; moreover, there is very little need to postulate a special kind of energy to explain the nervous impulse and its conduction, for of all the different activities of living cells that of conduction can be most readily described in terms of physics and chemistry.

The momentary change which makes the nervous impulse seems to consist in a depolarisation of the surface layers of the nerve fibre, a resulting increase in permeability, and an escape of ions from the interior of the fibre. The movement of ions brings about an increase of permeability in further sections of the fibre and a decrease in the sections previously active, so that the disturbance spreads but does not last for more than a brief time at any one point. The process is so simple in its essentials that Prof. Lillie has been able to construct model nerve fibres of iron wires coated with a film of passive iron and immersed in nitric acid. These models copy the behaviour of a nerve fibre with surprising fidelity.

For some time past, evidence has accumulated in favour of this explanation; it would be quite misleading to suggest that every detail of the conduction of the impulse is understood, but the broad outlines of the "membrane theory" have not been seriously challenged. The energetics of the process were worked out by Bernstein. The system loses free energy when the ions escape from regions of high to regions of low concentration, and ultimately this must be replaced by the metabolism of foodstuffs in the fibre. The splitting up of a large molecule into a number of smaller ones would suffice to restore the concentration differences upon which the movement of ions depends, and at various stages heat may be given out or absorbed from the surroundings. In no part of this scheme is there any need, or any opportunity, for the introduction of a special form of energy peculiar to nerves.

If the term "nerve-energy" is to be retained it might be used to mean the total potential energy in the neurone available for use in the transmission of impulses, but it is doubtful whether much would be gained by the measurement of this quantity. Prof. A. V. Hill has shown that the energy expended in the passage of a single impulse is extremely small, and the neurone is able to replenish its stores continually from the nutrient fluids which surround it. When failure of conduction occurs it seems to be due more often to a failure of the surface reaction than to an exhaustion of the store of potential energy in the fibre.

Interspecific Sterility.

In his letter on this subject (September 2, p. 312), Mr. Harrison states some interesting facts regarding the chromosome numbers in Salix. This appears to be the first case in plants where tetraploidy is accompanied by very little external change. Both tetraploid and hexaploid numbers in a genus have long been known, for example in Musa, but the point of my remark regarding interspecific sterility in crosses between diploid and tetraploid forms appears to have been missed. It is not that there is any difficulty in making such crosses in the first place. Usually they are easily made, but the result is a triploid form with an unstable chromosome content.

If such crosses between a diploid and a tetraploid species occur in Nature, they cannot lead to a permanent, stable form, except by apogamous reproduction. The hybrid may cross back with either parent, but this leads again to new and irregular chromosome numbers, with the result that, in the absence of apogamy, stability will be reached only when the extra chromosomes have been lost and the number has reverted to the diploid, or possibly in some cases to a balanced intermediate number. The two parental species, respectively diploid and tetraploid, will in the meantime each have carried on its own line of descent.

It follows that if a tetraploid form arises from a diploid species in Nature, it will continue to breed true, while its hybrids with the parent species will not give rise to a permanent line of descent unless there is apogamous reproduction. This is, for practical purposes, a condition of physiological isolation. *Spiranthes cernua* is a probable example of this sort, and there are many others. Once two such independent lines of descent are established, the divergence between them may go on increasing as fresh variations occur in each series.

Micro-Chemical Methods in the Practical Teaching of Chemistry.

In view of the strenuous efforts now being made by education authorities in this country to economise on educational expenditure, considerable interest attaches to Prof. Egerton Grey's letter on the application of micro-chemical methods in the teaching of chemistry (Nature, September 2, p. 309). During the War we conducted a course of practical instruction in chemistry in the Internment Camp for Civilian Prisoners of War in Ruhleben, and the difficulty of procuring large quantities of reagents led to the adoption of "Micro" methods wherever possible. Although we had at times forty students preparing for university examinations, the consumption of chemical reagents was extremely small in comparison with what would be required in the ordinary way. To give just one example, half a litre of nitric acid—a precious liquid in the camp—was found sufficient to supply the needs of these students for several months. One enterprising student fitted for himself a fully equipped "micro" laboratory in a tiny corner of his loft and undertook interesting research work.

A further advantage of the method is that the quantities involved are so small that the students can study the chemical properties of many of the rarer elements with great advantage to themselves and small expense to the laboratory. We are in hearty agreement with Prof. Grey as to the economic and educational advantages of the micro-chemical methods.

The Progression of Life in the Sea.[1]

By E. J. ALLEN, D.Sc., F.R.S.

DIFFERENT views are still held as to where life in the world had its origin, but no one questions that it began in close connexion with water. That it began in the sea, where the necessary elements were present in appropriate concentrations and in an ionised state, is an idea which appeals to many with increasing force the more closely it is examined. This view has been developed recently by Church[2] in his memoir on "The Building of an Autotrophic Flagellate," in which he boldly attempts to trace the progression from the inorganic elements present in sea-water to the unicellular flagellate in the plankton phase, floating freely in the water. The autotrophic flagellate, manufacturing its own food, he regards as the starting point from which all other organisms, both plants and animals, have sprung. To understand the first step in this progression, the passage from the dead inorganic to the living organic remains, is as it has always been, one of the great goals of science, not of biological science alone, but of all science. Recent research has, I think, thrown much light on the fundamental problems involved. In a paper published last year, Baly, Heilbron, and Barker,[3] extending and correcting previous work by Benjamin Moore and Webster,[4] have shown that light of very short wave-length (λ 200 $\mu\mu$) obtained from a mercury vapour lamp acting upon water and carbon dioxide alone, is capable of producing formaldehyde with liberation of free oxygen. Light of a somewhat longer wave-length (λ 290 $\mu\mu$) causes the molecules of formaldehyde to unite or polymerise to form simple sugars, six molecules of formaldehyde, for example, uniting to form hexose. The arresting fact brought out in these researches is that the reactions take place, under the influence of light of appropriate wave-lengths, without the help of any catalyst, either organic or inorganic. Where a source of light is used which furnishes rays of many wave-lengths, the simple reaction of the formation of formaldehyde is masked by the immediate condensation of the formaldehyde to sugar, but this can be prevented by adding to the solution a substance which absorbs the longer wave-lengths, so that only the short ones which produce formaldehyde are able to act.

When the formation of sugars is postulated, the introduction of nitrogen into the organic molecule offers little theoretical difficulty, for not only has Moore[5] shown that nitrates are converted into the more chemically active nitrites under the influence of light of short wave-length, but he maintains that marine algæ, as well as other green plants, can, under the same influence, assimilate free nitrogen from the air. Baly[6] also has succeeded in bringing about the union of nitrites with active formaldehyde in ordinary test-tubes by subjecting the mixture to the light of a quartz-mercury lamp.

If these results of the pure chemist are justified, they go far towards bridging the gap which has separated the inorganic from the organic, and make it not too presumptuous to hazard the old guess that even to-day it is possible that organic matter may be produced in the sea and other natural waters without the intervention of living organisms. We may note here, too, that if we take account of only the most accurate and adequately careful work, the actual experimental evidence at the present time requires the presence of a certain amount of organic matter in the culture medium or environment before the healthy growth of even the simplest vegetable organism can take place.

Let us then assume that we are allowed to postulate in primitive sea-water or other natural water organic compounds formed by the energy of light vibrations from ions present in the water, and see how we may proceed to picture the building up of elementary organisms. Without doubt the evolutionary step is a long and elaborate one, for even the simplest living organism is already highly complex both in structure and function. As the molecules grew more complex by the progressive linkage of the carbon atoms of newly formed carbohydrate and nitrogenous groups we must suppose that the organic substance, for purely physical reasons, assumed the colloidal state and at the same time its surface tension became somewhat different from that of the surrounding water. With the assumption of the colloidal state, the electric charges on the colloidal particles would produce the effect of adsorption and fresh ions would be attracted from the surrounding medium, producing a kind of growth entirely physical in character. We thus arrive at the conception of a mass of colloidal plasma differing in surface-tension from the water and increasing in size by two processes, one chemical, due to linkage of carbon atoms, the other physical, brought about by the adsorption of ions by the colloidal particles.

The difference of surface tension would tend to make the surface a minimum and the shape of the mass spherical. On the other hand, maximum growth would demand maximum exchange with the surrounding medium, and hence maximum surface. From the antagonism of these two factors, surface-tension and growth, there would follow, first, the breaking up of the mass into minute particles upon the slightest agitation, and, secondly, changes of form wherever growth involved local alterations of surface-tension, the latter would represent the first indication of the property of contractility.

So far we have considered only the process of the building up of the elementary plasmic particles, the anabolic process. Church, whose memoir already referred to I am now closely following, points out that these anabolic operations must from the beginning have been subject to the alternations of day and night, for during the night the supply of external energy is removed. "If during the night," he asks, "the machine runs down, to what extent may it be possible so to delay the onset of molecular finality that some reaction may continue, at a lower rate, until the succeeding day?" And his answer is: "The suc-

cessful solution of this problem is defined physiologically by the introduction of the conception 'katabolism,' as implying that energy derived from the 'breaking down' of the plasma itself . . . may be regarded as a 'secondary engine,' functional in the absence of light, and evolved as a last resort in failing plasma." Katabolism persists as the ultimate mechanism in the physiology of animal as contrasted with plant life, but if the suggestion just quoted is sound it originated, as the first "adaptation" of the organism, to meet the factor of recurring night and day. That the problem was successfully solved we know, but as to the mechanism of its solution we have no key. It is at this point, again to use Church's words, that the "plasma, previously within the connotation of chemical proteid matter, becomes an autotrophic, increasingly self-regulated, and so far individualised entity, to which the term 'life' is applied."

The elementary plasma is thus now fairly launched as an individual living organism, and the great fundamental problems of biology—memory, heredity, variation, adaptation—face us at each step of our further progress. We see in broad outline the conditions the advancing organism had to meet, we see the means by which those conditions were in fact met, we know that only those individuals survived which were able to meet them. Further than this we, the biologists of to-day, have not advanced. The younger generation will pursue the quest, and, with patient effort, much that now lies hidden will grow clear.

The differentiation of the growing particles of plasma into definite layers, which followed, seems natural; first the external layer, in molecular contact with the surrounding water, from which it receives substances from outside in the form of ions, and to which it itself gives off ions; beneath this the autotrophic layer to which light penetrates, and in which, under the influence of the light, new organic substance is built up; in the centre a layer to which light no longer penetrates. This central region, the nucleus, depends entirely on the peripheral layers for its own nutrition, and becomes itself concerned only with katabolic processes, those processes of the organism which depend upon the breaking down, and not the building up, of organic substance.

At an early stage in the development of the individual organism the spherical shape, which the organic plasma was compelled to assume under the influence of surface-tension, underwent an important modification, the effect of which has impressed itself upon all later developments. A spherical organism floating in the water and growing under the direct influence of light would obviously grow more rapidly on the upper side, where the light first strikes it, than it would on the lower side away from the light. There followed, therefore, an elongation of the sphere in the vertical direction, and the definite establishment of an anterior end, the upper end which lay towards the light and at which the most vigorous growth took place. In this way there was established a definite polarity, which has persisted in all higher organisms, a distinction between an anterior and a posterior end. With the concentration of organic substance which took the form of nuclei and reserve food supply, the specific gravity of the plasma would become greater than that of the surrounding water and the organism would tend to sink. The necessity, therefore, arose for some means of keeping it near the surface, that it might continue to grow under the influence of light. The response to this need, however it was attained, came in the development of an anterior flagellum. This we may regard as an elongation in the direction of the light of a contractile portion of the external layer, moving rhythmically, which by its movement counteracted the action of gravity, and acting as a tractor drew the primitive flagellate upwards towards the surface layers, into a position where further growth was possible. With the establishment of the flagellum an organ is produced which shows remarkable persistence in both the animal and vegetable kingdoms, and from the existence of the flagellated spermatozoon in the higher vertebrates, in accordance with Haeckel's biogenetic law that the individual in its development repeats or recapitulates the history of the race, we conclude that they also in their earliest history passed through a plankton flagellate phase.

Exactly at what stage in the history of the autotrophic flagellate the first formation of chlorophyll and its allied pigments took place we have no means of determining, but it may have been before even the flagellum itself had begun. This advance and the subsequent concentration of the pigments into definite chromatophores or chloroplasts doubtless increased immensely the efficiency of the organism in producing the food which was necessary to it. The recent work of Baly and his collaborators becomes here again of the first importance, and though the subject of the part played by chlorophyll in photosynthesis belongs rather to botany and chemistry than to zoology, I may perhaps, for the sake of completeness, be allowed to refer to it very briefly. I have already said that Baly brought about the synthesis of formaldehyde from carbon dioxide and water under the influence of rays of very short wave-length ($\lambda = 200\mu\mu$) from a mercury vapour lamp. He was also able to show that when certain coloured substances were added to the solution of carbon dioxide in water the same reaction took place under the influence of ordinary visible light. His explanation of this process is that the coloured substance known as the photocatalyst absorbs the light rays and then itself radiates, at a lower infra-red frequency corresponding to its own molecular frequency, the energy it has absorbed. At this lower frequency the energy thus radiated is able to activate the carbonic acid, so that the reaction leading to the formation of formaldehyde can and does take place. In the living plant this synthesised formaldehyde probably polymerises at once to form sugars.

Malachite green and methyl orange, as well as other organic compounds, were found to act as photocatalysts capable of synthesising formaldehyde, and Moore and Webster's work had previously shown that inorganic substances, such as colloidal uranium oxide and colloidal ferric oxide, can do the same. Chlorophyll in living plants may with some confidence be assumed to operate in a similar way, though no doubt the series of events is more complex, since the green pigment itself is not a single pigment, and others, such as carotin and xanthophyll, are also concerned.

We have tried to picture the gradual building up

from elements occurring in sea-water of a chlorophyll-bearing flagellate, capable of manufacturing its own nourishment and able to multiply indefinitely by the simple process of dividing in two. If we assume only one division during each night as a result of the day's work in accumulating food material, such an organism would be able in a comparatively short space of time to occupy all the natural waters of the world. But here we are met by a difficulty which is not easily overcome. Chlorophyll, the photocatalyst, the most essential factor in the building up of the new organic matter, is itself a highly complex organic substance, and in any satisfactory theory its original formation and its constant increase in quantity must be accounted for. Lankester[7] has maintained that chlorophyll must have originated at a somewhat late stage in the development of organic life, and has suggested that earlier organisms may have nourished themselves like animals on organic matter already existing in a non-living state. An alternative hypothesis, which in view of the recent work seems more attractive, is to suppose that the earlier organisms were either activated by some simpler photocatalyst, or that they received the necessary energy at suitable frequency directly from some outside source.

It must not be forgotten, also, that at the time these developments were taking place the conditions of the environment would in many ways have been different from those now existing in the sea. One suggestion of special interest that has been made[8] is that the concentration of carbon dioxide in the atmosphere, and hence also in natural waters, was very much greater than it is to-day. Free oxygen, indeed, may have been entirely absent, and all the free oxygen now present in the air may owe its existence to the subsequent splitting up of carbon dioxide by the action of plant life. With such possibilities of differences in the conditions in this and in so many other directions, may we not be well satisfied if, for the time, we can say that the formation of carbohydrates and proteids has been brought within the category of ordinary chemical operations, which can occur without the previous existence of living substance?

To return once more, however, to the free-swimming, autotrophic flagellate. In the early stages of its history the loss caused by sinking, and so getting below the influence of light and the possibility of further growth, must have been enormous. We may conceive a constant rain of dead and dying organisms falling into the darker regions of the sea, and thus a new field would be offered for the development of any slight advantages which particular individuals might possess. Under such conditions we may suppose that the holozoic or animal mode of nutrition first began in the absorption of one individual by another one, with which it had chanced to come into contact. If the one individual were more vigorous and the other moribund we should designate the process "feeding," and the additional energy obtained from the food might well cause the individual to survive. If the two individuals which coalesced were both sinking from loss of vigour, the combined energy of the two might make possible a return to the upper water layers, where, under the influence of light, growth and multiplication would proceed, and we should, I suppose, designate the coalescence "conjugation," or sexual fusion.

Other individuals, again, sinking in shallow water, would stick to solid objects on the sea-floor, while the flagellum continued to vibrate. The current produced by the flagellum under these conditions would draw towards the organism dead and disintegrating remains of its fellows, and again we should have ingestion and animal nutrition. At this stage we witness the definite passage from plant to animal life. A further stage is seen when a cup-like depression to receive the incoming particles of food is formed at the base of the flagellum, to be followed still later by a definite mouth.

The transformation from the plant to the animal mode of feeding can be seen in action by studying actual organisms which exist to-day. In the course of my work on the culture of plankton organisms there has flourished in the flasks, on several occasions, a small flagellate belonging to the group of chrysomonads, which was first described by Wysotzky under the name of *Pedinella hexacostata*, and to which I directed the attention of Section D at the Cardiff Meeting in 1920. The general form of Pedinella resembles that of the common Vorticella, but its size is much smaller. The body, which is only about 5μ in diameter, is shaped like the bowl of a wine-glass, and from the base of the bowl, which is the posterior end, a short, stiff stalk extends. From the centre of the anterior surface there arises a single long flagellum, surrounded at a little distance by a circle of short, stiff, protoplasmic hairs. Arranged in an equatorial ring just inside the body are six or eight brownish-green chromatophores or chloroplasts. In a healthy culture Pedinella swims about freely by means of a spiral movement of the flagellum, which functions as a tractor, the stalk trailing behind. The chromatophores are large, brightly coloured, and well developed, and the organism is obviously nourishing itself after the manner of a plant, like any other chrysomonad. But from time to time a Pedinella will suddenly fix itself by the point of the trailing stalk. The immediate effect of this fixing is that a current of water, produced by the still vibrating flagellum, streams towards the anterior surface of the body, and small particles in the water, such as bacteria, become caught up on the anterior surface, the ring of fine stiff hairs surrounding the base of the flagellum being doubtless of great assistance in the capture of this food. One can clearly see bacteria and small fragments of similar size engulfed by the protoplasm of the anterior face of the Pedinella and taken into the body. The organism is now feeding as an animal. In some of the cultures in which bacteria were very plentiful nearly all the Pedinella remained fixed and fed in the animal way, and when this was so the chromatophores had almost disappeared, though they could still be seen as minute dark dots. We can, as it were, in this one organism, see the transition from plant to animal brought about by the simple process of the freely swimming form becoming fixed.

In the group of dinoflagellates, also—the group to which the naked and armoured peridinians belong—

[7] "Tr[illegible]on Zoology," Part I, Introduction. London, 1909.

[8] Ca[illegible], "Life without Oxygen," *Science Progress*, vol. vi., 1912, p[illegible]

the same transition from plant to animal nutrition can be well followed by studying different members of the group. In heavily armoured forms, with a rich supply of chromatophores, nutrition is chiefly plant-like or holophytic. In those with fewer chromatophores there is, on the other hand, often distinct evidence of the ingestion of other organisms, and nutrition becomes partly animal-like. Among the naked dinoflagellates such holozoic nutrition is very much developed, and in many species has superseded entirely the earlier method of carbonic acid assimilation.

It is surprising how many structural features found in higher groups of animals make their first appearance in these naked dinoflagellates in conjunction with this change of nutrition, and we seem to be led directly to the metazoa, especially to the cœlenterata. In Polykrikos there are well-developed stinging cells or nematocysts, as elaborately formed as those of Hydra or the anemones. In Pouchetia and Erythropsis well-developed ocelli are found, consisting of a refractive, hyaline, sometimes spherical lens, surrounded by an inner core of red pigment and an outer layer of black; the whole structure is comparable to the ocelli around the bell of a medusa. In Noctiluca and in the allied genus Pavillardia a mobile tentacle, which is doubtless used for the capture of food, is developed. Division of the nucleus, with the formation of large, distinct chromosomes, has also been described in several of these dinoflagellates. With the tendency of the cells in certain species to hold together after division and form definite chains we seem to approach still nearer to the metazoa, until, finally, in Polykrikos we reach an organism which may well have given rise to a simple, pelagic cœlenterate. It is difficult to resist the suggestion put forward by Kofoid[9] in his recent monograph, that if to Polykrikos, with its continuous longitudinal groove which serves it as a mouth, its multicellular and multinucleate body and its nematocysts, we could add the tentacle of Noctiluca, and perhaps also the ocellus of Erythropsis, "we should have an organism whose structure would appear prophetic of the cœlenterata and one whose affinities to that phylum and to the dinoflagellata would be patent." Or it may be that the older view is the correct one here, and that the first cœlenterate came from a spherical colony of simple holozoic flagellates, arranged something on the plan of Volvox, in which the posterior cells of the swimming colony, in the wake of which food particles would collect, had become more specialised for nutrition than the rest.

As a purely plankton organism, swimming freely in the water, the progress of the cœlenterate was not great, and reached, so far as we know, no further than the modern ctenophore. The ctenophore seems to represent the culminating point of the primary progression of pelagic animals, which derived directly from the autotrophic flagellate. Further evolution was associated with an abandonment of the pelagic habit by a cœlenterate-like animal, and the establishment of a connexion with the sea-bottom, either by fixing to it, by burrowing in it, or by creeping or running over it. At a later stage many of the animals which had become adapted to these modes of life developed new powers of swimming, and thus gave rise to the varied pelagic life which we find in the sea to-day; but this must be regarded as secondary, the primary pelagic life, so far as adult animals were concerned, having ended with the evolution of the ctenophore.[10] Such is the teaching of embryology, the history of the race being conjectured from the development of the individual. In group after group of the animal kingdom, when the details of its embryology become known, the indications are the same—first the active spermatozoon, reminiscent of the plankton flagellate, then the pelagic larval stage, recalling the cœlenterate, and then a bottom-living phase.

It is in a ctenophore-like ancestor that we find the line of development to higher animal groups, and this ancestor must have been at one time widely distributed in the seas. Its immediate descendants are familiar to every zoological student in the well-known series of pelagic larval forms. Muller's larva, taking to the bottom, and in its hunt for food gliding over hard surfaces with its cilia, led to the flatworms; the Pilidium, developing a thread-like body and creeping into cracks and crevices to transfix its prey, gave rise to the nemertines. A trochophore, burrowing in soft mud and sand, developed a segmented body which gave it later the power of running on these soft surfaces, and became an annelid worm. Another trochophore, developing a broad, muscular foot, crept on the sand, and afterwards buried itself beneath it as a lamellibranchiate mollusc, or migrated on to harder surfaces as the gastropod and its allies. Pluteus, Bipinnaria, Auricularia, first fixing, as the crinoids still do, and developing a radial symmetry, afterwards broke free and wandered on the bottom as sea-urchin, star-fish, and cucumarian. Tornaria developed into Balanoglossus, the structure of which hints to us that the ascidians and vertebrates came from a similar stock. All the phyla thus represented derive directly from the free-swimming ctenophore-like ancestor, and only one considerable group, the arthropods, remains unaccounted for. The evolutionary history of an arthropod is, however, not in doubt. Its marine representatives, the trilobites and Crustacea, came directly from annelids, which, after their desertion of a pelagic life to burrow in the sea-floor and run along its surface, again took to swimming, and not only stocked the whole mass of the water with a rich and varied life of copepods, Cladocera, and schizopods, but gave rise to amphipods, isopods, and decapods, groups equally at home when roaming on the bottom or swimming above it.

Another important addition to the pelagic fauna we should also notice here. From the molluscs, creeping on solid surfaces, sprang a group of swimmers, the cephalopods, which have grown to sizes almost unequalled amongst the animals of the sea.

All these invertebrate phyla had become established and most of them had reached a high degree of development in the seas of Cambrian times. Among animals then living there are many which have survived with little change of form until to-day. One is almost tempted to suggest that the life which the sea itself

[9] Kofoid and Swezy, "The Free-living Unarmoured Dinoflagellata." Mem. Univ. California, 1921.

[10] There is perhaps a possibility that further knowledge of the embryology of Sagitta and its allies might make it necessary to modify this suggestion.

could produce was then reaching its summit and becoming stabilised. Since Cambrian times geologists tell us some thirty million years[11] have passed, a stretch of time which it is really difficult for our imaginations to picture. During that time a change of immense moment has happened to the life of the sea; but if we read the signs aright, that change had its origin rather in an invasion from without than in an evolution from within. From whence came that tribe of fishes which now dominates the fauna of the sea? It would be rash to say that we can give any but a speculative reply to the question, but the probable answer seems to be that fishes were first evolved not to meet conditions found in the sea, but to battle with the swift currents of rivers, where fishes almost alone of moving animals can to this day maintain themselves and avoid being swept helplessly away.[12] It was in response to these conditions that elongate, soft bodied creatures, which had penetrated to the river mouth, developed the slender, stream-lined shape, the rigid yet flexible muscular body, the special provision for the supply of oxygen to the blood to maintain an abundant stock of energy, and all those minute perfections for effective swimming that a fish's body shows. The fact that many sea fishes still return to the rivers, especially for spawning, supports this view, and it is in accordance with Traquair's classical discoveries of the early fishes of the Scottish Old Red Sandstone, which were for the most part fresh- and brackish-water kinds.

Having developed, under the fierce conditions of the river, their speed and strength as swimmers, the fishes returned to the sea, where their new-found powers enabled them to roam over wide areas in search of food, and gave them such an advantage in attack and defence that they became the predominant inhabitants of all the coastal waters, and as such they remain to-day.

The other great migration of the fishes also, the migration from the water to the land, giving rise to amphibians, reptiles, birds and mammals, must not be left out of account. The whales, seals, and sea-birds which, after developing on land, returned again to the waters and became readapted for life in them, are features which cannot be neglected.

And so we are brought to the picture of life in the sea as we find it to-day. The primary production of organic substance by the utilisation of the energy of sunlight in the bodies of minute unicellular plants, floating freely in the water, remains, as it was in the earliest times, the feature of fundamental importance. The conditions which control this production are now, many of them, known. Those of chief importance are (1) the amount of light which enters the water, an amount which varies with the length of the day, the altitude of the sun, and the clearness of the air and of the water; (2) the presence in adequate quantity of mineral food substances, especially nitrates and phosphates, and (3) a temperature favourable to the growth of the species which are present in the water at the time. Experiments with cultures of diatoms have shown clearly that if the food-salts required are present, and the conditions as to light and temperature are satisfactory, other factors, such as the salinity of the water and the proportions of its constituent salts, can be varied within very wide limits without checking growth. The increased abundance of plankton, especially of diatom and peridinian plankton, in coastal waters and in shallow seas largely surrounded by land, such as the North Sea, is due to the supply of nutrient salts washed directly from the land by rain or brought down by rivers. An exceptional abundance of plankton in particular localities, which produces an exceptional abundance of all animal life, is also often found where there is an upwelling of water from the bottom layers of the sea. These conditions are met with where a strong current strikes a submerged bank, or where two currents meet. Food-salts which had accumulated in the depths, where they could not be used owing to lack of light, are brought by the upwelling water to the surface and become available for plant growth. The remarkable richness of fish life in such places as the banks of Newfoundland and the Agulhas Banks off the South African coast, each of which is the meeting-place of two great currents, is to be explained in this way.

Attention has already been directed to the suggestion that fishes developed their remarkable swimming powers in rivers in response to a need to overcome the currents, and that they returned afterwards to the sea, where they preyed upon a well-developed and highly complex invertebrate fauna already fully established there. Their speed enabled them to conquer their more sluggish predecessors, while they themselves were little open to attack. With the exception of the larger cephalopods, which are of comparatively recent origin, and were probably evolved after the arrival of the fishes, there are few, if any, invertebrates which capture adult fishes as part of their normal food. Destructive enemies appeared later in the form of whales and seals and sea-birds, which had developed on the land and in the air.

And now in these last days a new attack is made on the fishes of the sea, for man has entered into the struggle. He came first with a spear in his hand; then, sitting on a rock, he dangled a baited hook, a hook perhaps made from a twig of thorn bush, such as is used to this day in villages on our own east coast. Afterwards, greatly daring, he sat astride a log, with his legs paddled further from the shore, and got more fish. He made nets and surrounded the shoals. Were there time we might trace step by step the evolution of the art of fishing and of the art of seamanship, for the two were bound up together, till the day when the trawlers and drifters kept the seas for the battle fleet.

There can be little doubt that in European seas the attack on the fishes in the narrow strip of coastal water where they congregate has become serious. A considerable proportion of the fish population is removed each year, and human activity contributes little or nothing to compensate the loss. We have not, however, to fear the practical extinction of any species of fish, the kind of extinction that has taken place with seals and whales. Fishing is subject to many natural limitations, and when fishing is suspended recovery will be rapid. There is evidence that such recovery took place in the North Sea when fishing was restricted by the war, though the increase which was noted is perhaps not certainly outside the range of natural

[11] Osborn, "Origin and Evolution of Life," 1918, p. 153.
[12] Chamberlin, quoted in Lull, "Organic Evolution," New York, 1917, p. 462.

fluctuations. Until the natural fluctuations in fish population are adequately understood, their limits determined, and the causes which give rise to them discovered, a trustworthy verdict as to the effect of fishing is difficult to obtain.

If such problems as these are to be solved the investigation of the sea must proceed on broadly conceived lines, and a comprehensive knowledge must be built up, not only of the natural history of the fishes, but also of the many and varied conditions which influence their lives. The life of the sea must be studied as a whole.

The Efficiency of Man and the Factors which influence it.[1]

By Prof. E. P. CATHCART, M.D., D.Sc., F.R.S.

THE subject of my address—the efficiency of the human organism and the factors which influence this efficiency—is in my opinion, one of the most important problems of the present day. It is a problem which cannot, however, be considered only from its physiological aspect if it is to receive adequate consideration; its implications are much wider, reaching right down to the very basis of our daily lives. As I am no expert in industry or economics, I shall confine my attention so far as possible to the problem from the physiological side, and leave to others the sociological application.

The term "efficiency" has become a mere catchword, bandied about by people who have not the faintest idea of what the word connotes. Practically it has come to mean, to the average man in the street, the mythical improvement which is to be anticipated from some change in workshop or office organisation—a bigger and better result at a smaller cost. The word has a very definite meaning in engineering science and this meaning has been transferred from the inanimate machine to the living organism. In the case of the engine, the problem is relatively simple, as the number of interfering factors is not great, but the solution of the problem in the case of the organism is beset with many difficulties, as the interfering factors are numerous and varied. Two types of efficiency are spoken of in connexion with the animal body. One type is the mechanical efficiency in the engineering sense, *i.e.* the ratio which exists between the heat equivalent of the external muscle work done and the energy output of the subject during the performance of the work in question. This is a problem which has attracted many workers, and there seems to be a general consensus of opinion that the efficiency of man in the performance of external work is about 20 per cent. gross and 25 per cent. net. The other type of efficiency is that which is called industrial or productive efficiency, where the capacity of the individual to perform effective work is dealt with, judging the capacity of the individual by, for example, his output in unit time. So far as the worker himself is concerned the whole object in industrial efficiency is undoubtedly to get the greatest output with the minimum of effort. The determination of the mechanical efficiency is fairly readily carried out, but it is very difficult to get an accurate gauge of the industrial efficiency. At bottom they are closely related, and both are physiological problems.

The leaders of industry have not been slow to accept and utilise the gains of science in the realm of inanimate things, but they have been slow to recognise the fact that there is a science of physiology which deals with the man who controls the productive machinery. New inventions may completely revolutionise shop equipment, good machines may be replaced by better, and better by still better, but man remains almost as immutable as the ages. Physiological evolution is infinitely slow, and man has not yet become "an affectionate machine-tickling aphid."

It is but a little more than a hundred years since this country was industrialised, and we are still reaping the aftermath of the terrible conditions which then reigned, when the great centres of industry were swamped with country dwellers who poured into the towns in the race for wealth. Few realise the hopelessly unphysiological conditions which developed in the methods of work, the hours and conditions of work, the housing. The following citation from Robert Owen gives a good idea of the conditions ruling in the early years of last century in one of our staple industries. "In the manufacturing districts it is common for parents to send their children of both sexes at seven or eight years of age, in winter as well as summer, at six o'clock in the morning, sometimes, of course, in the dark, and occasionally amidst frost and snow, to enter the manufactories which are often heated to a high temperature and contain an atmosphere far from being the most favourable to human life, and in which all those employed in them very frequently continue until twelve o'clock at noon, when an hour is allowed for dinner, after which they return to remain, in a majority of cases, till eight o'clock at night." Six till eight, with a break of one hour—a fourteen hours' day, and fifteen was not unknown. Owen in the article from which I have quoted, was petitioning Parliament, asking what? That a twelve hours' day be instituted, to include one and a half hours for meals, and that no child should be employed until the age of ten was reached. He pointed out in the course of the article that the results from the manufacturers' point of view would be better with a twelve hours' day (*i.e.* that the industrial efficiency, in modern words, would be improved).

Yet we wonder that the offspring of stock descended from workers under these conditions, which certainly improved as the century advanced, but were far from ideal, gave the high yield of C3 lads recorded in the National Service Report. We might have been prepared for the disclosure, as the pre-war records of countries with conscription showed that the number of rejections for the Army of town and factory workers was far in excess of those for men drawn from country districts. But evidence of the state of the national

[1] From the presidential address delivered to Section I (Physiology) of the British Association at Hull on Sept. 8.

physique is not confined to these war figures. Sir George Newman, in his valuable and interesting Report on Preventive Medicine, has directed attention to the enormous amount of time which is annually lost through sickness. The minimum average amounted to 14,295,724 weeks (or a period upwards of 270.000 years) of sickness per annum, and this figure did not include absence from work due to maternity benefit, sanatorium treatment, or absence for less than four days per patient. This is the evidence of the National Health Insurance.

The design of the organism which has to stand the strain is not at fault. It is an organism which, in the language of the engineer, is abundantly supplied with factors of safety, and has an over-all high factor of safety. The body is not designed merely to perform the minimum amount of work or to stand the minimum strain, there is always a reserve. The perfect co-ordination of the different parts of the organism is required, because the human being is capable of intense muscular exertion for short periods. The intensity of the work is, as a general rule, inversely proportional to the length of time during which it must be carried out.

If, in the human organism, we were concerned merely with the co-ordinated action of a series of effectors, with the capacity of a certain group of muscles to perform a given amount of work, the solution of the problem would be relatively simple. But we are dealing with a living organism, capable not only of doing work, but of repairing the worn-out parts, as and when required. Further, we are dealing with an organism which varies not only in its capacity to perform work, but in its "will to work." We are dealing with a subtle organism which has a whole series of protective mechanisms at its command, an organism which can be fatigued and rendered useless, as a working unit, by an amount of work on a particular day which on another day it can perform with the utmost ease and without apparent fatigue.

The efficiency of a man is not merely dependent on the amount of work which can be performed by his muscles; the circulatory, respiratory, and nervous systems are of equal importance, and all are intimately related. In spite of the many and varied stresses and strains to which the organism is subjected in the course of life, as the result of the many factors of safety, unless the overloading is excessive, too frequent or too long continued, the organism, so long as it remains physiological, is practically unaffected by ordinary hard work.

If we turn now to the consideration of the factors which influence the efficiency, both in the mechanical and the industrial sense, we find that the main controlling factor is undoubtedly the condition known as fatigue. Fatigue is a word just as frequently used as efficiency, and yet it is almost impossible to give an accurate definition of the term. Generally speaking, it is to be regarded as the antithesis of efficiency.

The study of the metabolism has given little or no clue so far to the real nature of fatigue. Benedict and I carried out a certain amount of experimental work on this phase of the question. Our results show that the subject may be on the very verge of absolute collapse, and yet so far as the metabolic determination goes, there is no very marked evidence of diminished efficiency in the mechanical sense. In an experiment with M. A. M., who, in the post-absorptive state, rode on a bicycle ergometer for nearly four and a half hours until on the verge of collapse, doing 208,000 kilogrammetres of external work during the time, the metabolism was determined six times during the riding period with the following result:

TABLE I.

Time.	Oxygen Consumption per min in c.c.	Rate of Work, revs per min	Net Efficiency in per cent.
8.30 A.M. (start)			
9.00 ,,	1967	91.3	23.1
9.15 ,,	1946	91.4	23.3
10.30 ,,	1969	91.7	23.2
11.15 ,,	1948	90.3	23.2
12.00 noon	2003	89.0	21.7
12.45 P.M.	1899	78.2	21.3

It will be noted, as might be expected, that there is some slowing of the rate at which the work is done, but the diminution in the net efficiency, in spite of the fact that the subject admitted he was completely done at the conclusion of the last determination, is not striking.

Obviously, then, the capacity to carry on is limited by the genesis of fatigue. But it is equally obvious in practice that a man may be engaged in strenuous labour for many hours without acute signs of impending exhaustion. How is this condition attained? There are at least four factors which, to my mind, play predominant rôles in the attainment of maximum efficiency, namely, the rate of the performance of work, the amount of rest offered or taken by the subject, the rhythm with which the work is performed, and the work habits developed by the worker. Although I shall attempt to examine each of these factors separately, it is not to be inferred that they can really be considered as independent phenomena. As a matter of fact, they are all intimately related, and usually merge into one another.

Of these four factors probably most attention has been devoted to the rate or speed at which work is carried out. Benedict and I found, for example, working with a carefully calibrated bicycle ergometer, that there was a very close connexion between the speed at which work was done and the mechanical efficiency. There was a very definite falling off with increased speed, as the following table shows. Unfortunately it was impossible to get our subject to pedal slower than 70 revolutions per minute.

TABLE II.

Revolutions per min.	Gross Efficiency.	Revolutions per min.	Gross Efficiency.
70	20.6	110	17.6
80	20.0	120	16.9
90	19.2	130	16.1
100	18.4	..	..

We found further that, if the amount of effective muscular work done was kept constant, that the efficiency fell with an increase of speed. Thus with effective work equivalent to 1.95 calories performed

at the rate of 90 and 124 revolutions per minute respectively; with the lower speed the net efficiency was 22·6 per cent., whereas with the higher speed it fell to 15·7 per cent. Or again, with effective work of 1·58 calories at 71 and 108 revolutions per minute, the efficiency was 24·5 per cent. and 15·6 per cent. respectively; and finally, with effective work of 1·35 calories at speeds of 71, 94, and 105, the efficiencies were 23·1, 20·4, and 17·0 per cent.

A. V. Hill has also recently dealt with this problem in a most interesting piece of work, where the activity was strictly confined to the biceps and the brachialis anticus. He demonstrated very clearly that, in spite of the fact that the slower the contraction the greater was the amount of work done, all the advantage thus gained was rapidly neutralised and dissipated as the result of the slow contraction necessarily causing an increased degradation of energy in the way of physiological changes resulting from the maintenance of contraction It thus followed that a slow contraction, powerful though it might be, was not necessarily one of high efficiency. Hill found that the maximum efficiency was very rapidly attained, the optimum for the muscles investigated being apparently just less than one second, but the fall which followed, as the duration of the contraction increased, was a comparatively slow one. On account, therefore, of the blunt nature of the curve, the efficiency remained more or less constant over a wide range of speeds.

The load has obviously a direct connexion with the speed at which work is done, but it has also a relation to efficiency. Benedict and I found, for example, that both the gross and net efficiencies within the limits of our experiments increased with the load The probable explanation of this result is that when light work is carried out, maintenance or physiological requirements which have to be covered form a large proportion of the total energy output, a balance which is steadily altered as the amount of external effective work done increases.

On the other hand, when the loads become excessive there is a definite falling off, both in gross and net efficiencies Laulanié, who also investigated this question, found that at voluntarily selected speeds, with steadily increasing load, the external work done rose with decreasing speed until the load became excessive. He maintained that there were two optima, (*a*) an economic optimum at 4 kilo. load with high efficiency and a low oxygen consumption per kilogrammetre, and (*b*) a mechanical optimum between 8 and 12 kilo. load when the output in unit time was highest. The following table from Laulanié makes his point clear:

TABLE III.

Resistance in kilos .	1	2	3	4	5	6	8	10	12	15
Speed adopted, metres per sec .	1·49	1·07	0·80	[illegible]	0·51	0·44	0·37	0·29	[illegible]	0·13
Work done, kilogrammetres per 5 min.	448	642	726	778	812	853	896	905	900	570
Oxygen intake in c.c. per kgm	3·51	2·44	2·17	2·14	2·23	2·25	2·43	2·53	3·12	5·31
Efficiency per cent . .	14·1	20·4	22·9	23·3	22·3	22·1	20·4	19·7	17·0	9·4

It will be noted that when the load becomes excessive the efficiency rapidly falls away. This means that, although the effort may be continued as strenuously as before, and although the physiological cost of the effort remains at a very high level, the amount of external work done is reduced to a very low figure. The static element in the muscular effort has become dominant, and static expenditure is parasitic on dynamic work. The more static the work becomes the greater is the fall in the efficiency. Personally I am of the opinion that the severity of muscular work, *qua* the organism as a whole, is a function of the static component of the effort made. Fatigue, *i.e.* inability to carry on, is more readily induced by static work than by either positive or negative work. The following figures, from experiments which I have carried out with Miss Bedale and G. McCallum, show clearly this diminution in efficiency as the static element in the work is increased:

TABLE IV

Pulls per min	Kgm per min	Cost in grm cals per kgm p sq. m	Net Efficiency per cent.
32	40	16	8·0
12	15	17	7·5
6	7·5	20	6·0
4	5·0	31	3·0+
3	3·75	38	3·0
2	2·5	68	2·0-
1	1·25	146	1·0

Very closely allied with the rate of working is the rhythm with which the work is performed. Although they are not identical phenomena, they are so closely related that the habit of work may be considered along with rhythm. Every one is well aware that once a rhythm, or the proper co-ordination in the play of a set of muscles in the performance of some definite act, is mastered, not only is the energy expenditure reduced by the exclusion of numerous extraneous muscular activities, but there is an actual enhancement of the ease with which we perform the specified act. It is not a mere question of rate. In a series of experiments which I carried out with Burnett, the subject, working on a specially geared ergometer, was allowed to select his own rate of working, the load being varied from nothing to 4 kilos. At each change of load the subject was directed either to work rapidly or very slowly, and after a period of such work was told to adopt the rate he liked best. As the following table (Table V.)

TABLE V

Load in kilos	Rate of Work per min voluntarily selected			
	Exp I	Exp II	Exp III	Exp IV (Immediately after 1 hour's work at rate of 45 per min)
0	78	80	83	
1	80	79	79	71
2	81	80	81	
3	80	78	83	73
4	82	77	78	

shows, the rhythm of work was practically identical for all loads. This occurred under all conditions, provided the working spells were not of too long duration. If the work were continued over a long period, the rhythm tended to alter, to increase in speed, and if the subject became really tired, periods of rapid movement alternated with periods of slow movement.

The rhythm adopted, although it may suit the worker, is not of necessity the series of muscle movements which lead to the least expenditure of energy.

Most probably the rhythm selected is only in small part due to the worker's physical configuration; in greater part it is evolved in imitation of some more experienced or older worker. The average workman is not so much concerned with the diminution of the physiological cost in the performance of a given act as in the reduction of conscious effort. It is not, of course, suggested that the methods adopted by workers independently are the perfect methods, and that proper investigation will not discover better and easier methods of performing certain given operations. If newer and more economical methods are to be developed and brought into operation, the only real chance will be to segregate the newer young workers.

There is good evidence, that of Mosso, for example, that both resting and working, in addition to the individual muscle rhythm, there is a definite variation in the course of the day in the capacity to carry out work; that, in other words, a diurnal rhythm exists. There is a certain amount of evidence also in favour of the view that a seasonal rhythm exists. Further, when efficiency is measured in terms of output, it is found that there is a definite rhythm in output during the course of the working day and of the working week. This type of curve is not peculiar to any one industry. The total weekly output curve with the low Monday effect and the sharp fall on Saturday resembles in general shape the daily output curve. The main point about these curves is that they seem to demonstrate the absence of progressive fatigue from overwork, which would have been deduced had there been a sharp rise at the commencement of the week, followed by a steady fall.

The third of the potent factors in the control of fatigue is rest. If work is done, rest is ultimately imperative. Rest not merely relaxes the muscle, allowing a more thorough and complete removal of the waste products and a more abundant supply of oxygen, but it removes the strain of attention. Rest is best obtained, not by simple quiescence, but by change of posture; slow movement of another type to that which produced the fatigue will, unless the organism is tired practically to complete exhaustion, give the most beneficial results.

So far, little attention has been paid to the duration of the rest period in relation to the work done. As a general rule, it may be said that, in the majority of occupations, although the hours of labour are continuous, the actual spells of hard manual work are discontinuous, either due to the fact that certain operations are intermittent in their severity, that supplies of material are not constant, or that, if these more or less natural conditions do not operate, rests at irregular intervals are deliberately taken by the operative. So far as I am aware there is only one type of hard work where a definite rest period is laid down as part of the exercise, namely, in Army route marching.

So much, then, for the ordinary effector factors. There are many other factors directly concerned with the efficient action of the organism, some directly influencing the internal economy of the body, others acting more directly on the organism from the environment.

One of these factors is the state of the nutrition. It may be definitely stated that an insufficient intake of food or the consumption of poor or inadequate food is one of the chief sources of general inefficiency. The capacity of the body to store reserve food material which will meet the daily demands for energy and leave a surplus is another of the vital factors of safety. The much more important problem is unfortunately only too common, the influence of chronic undernutrition, a condition which lowers efficiency, not merely in the actual performance of muscular work, but by inducing an increased susceptibility to disease. This is a question which has never received the attention which its importance demands, largely on account of the immense difficulties of carrying out the investigation in a practical manner. As the direct result of the war, we have the records of at least two sets of observers. Benedict and his co-workers investigated the problem, using a group of twelve men, comparing them with a similar group drawn from the same class. In the experimental group the food intake was reduced, so that there was a loss of 12 per cent. of the body weight. Although the experiment was carried on for more than four months, the diminution in muscle power, so far as laboratory tests were concerned, was not great. The subjective impression, however, of the subjects was that they felt weaker and less capable.

The other recorded experiment is that of the condition in Germany during the war years. A general statement of the effects of the blockade is contained in a long document prepared by the German Government (dated December 1918). Admittedly the document was prepared for a specific purpose; but, after making all allowances, the record of the far-reaching effects of chronic underfeeding is valuable. Apart from the increased death rate, the increased liability to disease, and the slow recovery from the attacks of disease, the document definitely states that the working capacity of the people was reduced by at least one-third. Evidence would also indicate that it is not only the quantity but the quality of the food consumed which plays a part in the fitness of the individual to perform hard muscular work.

Another factor which plays an enormous rôle in the general efficiency is the response of the organism to the multiple psychic imponderabilia which compose such a large part of the average environment. When we are dealing with the efficiency of the human organism, male and female, we are dealing with individuals whose performance is neither uniform throughout the year nor from week to week, nor even from hour to hour. We have to deal with an organism, as I have already mentioned, which is not only under physical control, but is very responsive to psychic influences. Man is, in the main, a psychic chameleon.

In this connexion monotony of work must be considered. Although there may be a close relationship between monotony and fatigue, as generally recognised, they are not identical. The temperament of the operative plays an enormous part in determining whether or no any particular operation is a monotonous one. As Munsterberg has shown, it is extremely difficult, if not impossible, for an outsider to determine what is a monotonous operation.

There are many other factors which play a definite

and important rôle in the maintenance of efficiency, such as lighting, heating, ventilation, the mode of life led by the worker outside his definite hours of labour, his housing, etc. Many of these factors have been partially examined. Thus Leonard Hill has carried out a great deal of valuable work on the influence of the cooling power of the air. Vernon has collected much interesting evidence, which shows that there is a very definite relation between the efficiency, as measured by output, and the temperature of the working place. The output in the hottest weather was about 30 per cent. below that when the weather was coldest. He also observed an apparent connexion between the relative humidity of the air and the efficiency of the worker. The efficiency, as might have been expected, was apparently greatest when the relative humidity was low. Elton has reported on the influence of lighting in silk weaving. He found that the output was lowest when artificial light was used. He stated that even when electric light of sufficient intensity was used, the output was about 10 per cent. lower than the daylight value. The actual equipment of the factories, the provision of seats of suitable size, height, etc., the design of the machines, and so on, all play their part, as is shown by the many records, particularly from the United States.

In other words, the real over-all industrial efficiency of the worker cannot be causally related to any single factor. It is not the mere capacity of the individual to perform so many kilogram-metres of work in a given time with the smallest expenditure of energy. The quest of efficiency calls for the closest and most intimate co-operation between the scientific investigator, the employer, and the employee, and it can only be satisfactorily attacked when mutual distrust of motives, capacities, and methods is stilled.

The Total Solar Eclipse of September 21.

By Dr. A. C. D. CROMMELIN.

THE failure of the Christmas Island eclipse expedition is a great astronomical disappointment. Messrs. Jones and Melotte have devoted ten months or more to it, and hoped to secure useful photometric results for connecting the northern and southern stellar magnitude scales in addition to the eclipse work. The climate, however, proved unexpectedly unfavourable, and practically nothing could be done.

On the other hand, the conditions appear to have been ideal right across Australia, and enthusiastic reports have come from Wollal (West Coast), Cordillo Downs (centre), and Goondiwindi and Stanthorpe (Queensland). The Einstein problem was studied at Wollal by the Lick Observatory party under Prof. Campbell, and that from Toronto under Prof. Chant. Mr. Evershed also finally selected this station in preference to the Maldives, and is believed to have undertaken the same investigation in addition, doubtless, to spectroscopic work. Prof. Dodwell, the Government Astronomer at Adelaide, had the use at Cordillo Downs of a tower telescope lent by the Lick Observatory for the Einstein problem; the New South Wales astronomers were in Queensland and did some spectroscopic work; they intended also to make Einstein investigations, but the telegrams do not allude to these.

It is well to point out that the test of the Einstein theory does not depend wholly on the results of this eclipse. The plates secured in the 1919 eclipse at Principe and Sobral settled definitely that at least the half-shift was present, while the two cameras with the best definition gave values very close to the Einstein value. Further, the star field in that eclipse was the best along the whole extent of the ecliptic, the stars in the present eclipse being much fainter. There are, however, two circumstances that should add weight to this eclipse: (1) that some of the observers were pointing directly on the stars, avoiding the use of a coelostat or other mirror; (2) that the plan was being tried of photographing another star-field *during totality*, thus obtaining an independent scale value for the plates, which gives a much larger coefficient to the Einstein displacement in the equations of condition.

Probably weeks or months must elapse before the Einstein results are to hand.

The corona is said to have had four long streamers, one extending to three solar diameters, which is more than the average, though by no means a record.

Prof. Chant reports that the shadow bands were photographed. Prof. Kerr Grant, of Adelaide University, made measures at Cordillo by the photoelectric cell of the relative brightness of the sun and the corona. The results with this very sensitive instrument should be more trustworthy than previous determinations.

The next two total eclipses (1923, September, and 1925, January) are visible in the United States; 1926, January, in Sumatra, etc., and 1927 in England and Norway.

Obituary.

PROF. ALEXANDER SMITH.

ALEXANDER SMITH, emeritus professor of chemistry in Columbia University, New York, died in Edinburgh on September 8, aged fifty-seven. Smith was born in Edinburgh, and entered the University there in 1882, where he studied mathematics under Chrystal, natural philosophy under Tait, and chemistry under Crum Brown, graduating as B.Sc. in 1886. During the following three years he attended the University of Munich, working in Baeyer's laboratory, chiefly under the direction of Claisen, and obtained the degree of Ph.D. in 1889.

After a year spent as assistant in the chemistry department of the University of Edinburgh, Smith was offered the chair of chemistry and mineralogy in Wabash College, Indiana, a post which he held for four years. In 1894 he became assistant professor of

chemistry in the University of Chicago, and rose through intermediate grades to that of professor and director of general and physical chemistry in 1903. Here his extraordinary gifts as organiser and teacher found ample scope. His 'Laboratory Outline of General Chemistry' was published in 1899, since when at short intervals new text-books or new editions flowed from his pen. Each book had in view the requirements of students of a definite stage of development, and all were characterised by an orderliness of method, combined with an originality of thought, which have made them popular not only throughout the English-speaking world but also as translations in almost every country where science is studied. An even wider field was offered to him in the principal chair of chemistry in Columbia University in the City of New York, where he became director of the department of chemistry. Here he may be said to have revolutionised the methods of teaching and the organisation for chemical research.

Smith at the outset of his career was an organic chemist, and until 1902 his published papers are all concerned with organic topics, chiefly the chemistry of diketones, the benzoin reaction, and, generally, the action of potassium cyanide as a condensing agent. After 1902 his work is inorganic and physico-chemical, the physical character of his investigations becoming more and more marked with the lapse of years. An admirable series of papers on the liquid and amorphous modifications of sulphur formed the first-fruits of his cultivation of this new field. Chiefly in conjunction with A. W. C. Menzies, now professor of chemistry at Princeton, Smith published a long series of papers on vapour pressures, many new devices for their exact measurement and for the measurement of boiling-points under standard conditions being described. Among the valuable data obtained may be noted the exact determinations of the vapour pressure of mercury from 250° to 435° C. The vapour pressures of dissociating substances such as ammonium chloride, calomel, and phosphorus pentachloride were also measured and discussed, particularly in connexion with the unexpected values obtained when the substances were perfectly dry. His scientific merit was recognised by his election to membership of the National Academy of Sciences, and to the Presidency of the American Chemical Society. In 1919 the honorary degree of LL.D. was conferred upon him by the University of Edinburgh.

Smith was a most genial personality, a pleasant companion, and a delightfully amusing talker. He was filled to overflowing with energy, which in the end proved his undoing. A breakdown owing to overwork, complicated by a serious operation, forced him after a year's leave to relinquish his chair, and his death at a comparatively early age deprives his science of a great teacher whose name will not soon be forgotten.

J. W.

Dr. Sophie Bryant.

By the death of Dr. Sophie Bryant in the Alps last month the educational world has lost a great personality. As mathematician, philosopher, Irish patriot, suffragist, and, above all, as a teacher and pioneer in education, she had gained distinction in so many fields that it is difficult to give any adequate account of her in a few paragraphs.

Mrs. Bryant in her own person gave the lie to the old conception of the unwomanly "bluestocking." Her greatness of intellect was shot through with a warmth of genial humanity and an endearing charm that those who knew her can never forget. She came of a scholarly stock: her father, Dr. Willock, a clergyman of the Church of Ireland in Co. Fermanagh, worked in the cause of education there. After his death the family moved to London, and his brilliant daughter distinguished herself by obtaining, at the age of sixteen, first-class honours in the Senior Cambridge Local Examination, with distinction in mathematics, and an Arnott scholarship at Bedford College. It was only after her marriage and early widowhood that she became acquainted with Miss Buss, and, having joined the staff of the North London Collegiate School in 1875, was one of the first to take advantage of the opening of London University degrees to women. After matriculating in honours in 1879 (with the distinction of being placed second on the list), in two years she had obtained the B.Sc. with honours in mathematics and moral science, and three years later was the first woman to gain the doctor's degree of London University, her subject being mental and moral science. She used to relate an amusing story about this: one of the two examiners wrote to his colleague, "There's a very good man in," the other, who knew Mrs. Bryant, replied, "Your man's a woman!"

Ten years later, in 1894, Mrs. Bryant was appointed to sit on the Royal Commission for Secondary Education, of which Lord Bryce was chairman. In 1900 she became a member of the Consultative Committee of the Board of Education, and in the same year took her seat on the Senate of London University. From 1908 to 1914 she was a member of the London Education Committee.

During all this time she was, in a very real sense, a "guide, philosopher, and friend" to her pupils at the North London Collegiate School; the writer of this article is one of many whose debt to her in this respect is beyond all reckoning. When in 1895 Mrs. Bryant succeeded Miss Buss as head-mistress, her mathematical teaching perforce devolved to a large extent on her colleagues, but she remained the guiding moral force in the school, explicitly through her Scripture lessons and weekly addresses, but *implicitly* in all that she did. She was a pioneer in the revitalising of Scripture teaching, bringing to bear on religious instruction the same psychological insight and width of outlook by which she and her fellow-reformers brought life into the dry bones of the educational curriculum. Of this work she has left a permanent memorial in her books: "The Teaching of Morality in the Family and the School," "The Teaching of Christ in Life and Conduct," "How to read the Bible in the Twentieth Century," "Moral and Religious Education."

Mrs. Bryant was a devoted Irishwoman, and perhaps no honour pleased her more than the degree of doctor of literature, *honoris causa*, bestowed upon her by Trinity College, Dublin, when first it opened its degrees to women. Her love of Ireland also found expression in her writings: "Celtic Ireland," "The Genius of the

Gael," and the book on the Brehon laws, barely completed before she left England for the last time, which is to be published shortly under the title "Liberty, Order, and Law under Native Irish Rule," dedicated to "the Rebuilders of Ireland United and Free"

Like Plato's philosopher "the spectator of all time and all existence," Mrs. Bryant by her clearness of vision and width of outlook made it impossible to think of anything mean or ungenerous in association with her. She was a great teacher, a great personality, and a splendid friend, a perpetual source of inspiration and joy to those who knew her. Her spirit lives, not only in the school she helped to build (advancing it alike in science and the humanities till it stood first among a band of sister-schools), but in all those who owe to her a grasp of the ideal, an understanding of the meaning and value of life.

M. H. W.

WE much regret to announce the death on September 21, at the age of fifty-eight years, of Prof. F. T. Trouton, F.R.S., emeritus professor of physics in the University of London.

THE secretary of the Institution of Electrical Engineers informs us of the death of Mr. Louis Heathcote Walter, a member of the Institution staff, who had been editor of *Science Abstracts* since 1903.

Current Topics and Events.

IT was no mean occasion that the members of the Yorkshire Philosophical Society met together on Wednesday, September 20, to celebrate. To have held aloft the lamp of learning for a hundred years, and to have conserved and preserved, amid all the changing scenes and conditions of a century, the ancient ruins of St. Leonard's Hospital, the Roman Wall and the Multangular Tower, the ruins of St. Mary's Abbey, and built up a museum second to none in the provinces in the richness of its collections, is indeed a record of which the society might feel justly proud. Moreover, during this period the society has been instrumental in founding two most powerful and wide-reaching institutions, for the Yorkshire Museum was the birthplace and cradle of the British Association and the younger Museums Association. It was therefore very fitting that the society should celebrate the occasion of its hundredth birthday and receive the congratulations of its honoured patron His Majesty the King, and various universities and learned societies. Mr. W. H. St. Quintin, the president, occupied the chair, and was supported by the vice-presidents and council, the hon. treasurer (Mr. Edwin Gray), the hon. secretary (Mr. C. E. Elmhirst), the keeper of the museums (Dr. Walter E. Collinge), and the Rt. Hon. the Lord Mayor, the City Sheriff, Aldermen, and Council. After briefly tracing the history of the society, the work it has done, and recounting its benefactors, Mr. St. Quintin pointed out that a considerable sum of money will be necessary if the society is to continue its good work for the advancement of science, and he asked that in this, its centenary year, a substantial amount should be forthcoming. Addresses were read or presented from a number of leading scientific societies and other national institutions. His Highness the Maharaj Rana of Jhalawar offered congratulations on behalf of the Indian Empire, and congratulatory messages were received from other distinguished people. At the close of the meeting a highly picturesque procession was formed to the Cathedral, where a special evensong was held, the Lord Bishop of Beverley officiating. The delegates and visitors were later entertained to dinner in the De Grey Rooms, after which a conversazione was held in the Yorkshire Museum and the Tempest Anderson Hall.

ACCORDING to the September issue of the *Decimal Educator*, the official organ of the Decimal Association, the metric system has been or is soon to be adopted in Greece, Poland, Haiti, and Japan, while the Russian government is rapidly introducing it into its administrative departments. The British Chamber of Commerce in the Argentine and the Consul for Bolivia again warn British exporters of the futility of quoting in pounds, shillings, and pence for amounts specified in Imperial weights and measures. Mr. W. A. Appleton, secretary of the General Federation of Trade Unions, states that "these weights and measures of ours cheat the home buyer and arouse the suspicion of the foreigner," and asks how many buyers know the difference in weight of a peck of potatoes and a peck of peas. The Lancashire cotton market has ceased to quote cotton in sixty-fourths of a penny and now gives the price in hundredths, but we still appear likely to fulfil the prediction of Augustus de Morgan and "adopt the metric system when every other country has done so." Sir Richard Gregory, president of the association, recommends in an introductory article that the metric system should be made the sole legal system in all departments of State, and the nation thus prepared for its general introduction, which is bound to come in its time, as it is foolish to expect the world to adopt the Imperial as an international system.

A REPORT has been received that the ruins of an ancient city of great extent have been discovered in Colombia by the South American Archæological Expedition from Chicago. As yet the information is scanty, but Dr. J. A. Mason, the leader of the expedition, states that the ruins are situated in the Province of Magdalena, twenty miles south of Santa Marta. "There must have been a tremendous population here at one time, as the country is covered with house sites. The country is very mountainous, and the houses, which were of wood, were built on terraces made with retaining walls." It is not certain that these terraces may not be those used in terraced cultivation, but Colombia has been little explored, and a detailed report of the excavations must be awaited before the value of the discovery can be estimated.

AFTER having been lost for centuries the remains of the ancient monastery of Nendrum, on Mahee

Island, Strangford Lough, have been brought to light by the agency of the archæological section of the Belfast Natural History and Philosophical Society. Founded about A.D. 150 it is mentioned in connexion with St. Patrick, and it held for centuries an important position in the Celtic Church. The discovery of the site is due to Bishop Reeves. The most remarkable part of the ruins is a long stone causeway which was probably the monks' walk. Near the north door of the Church a fragment of an important old Norse inscription has been discovered. Words meaning "Prime Abbot" and "Church of Christ" have been interpreted by Prof. Macalister of Dublin. Every effort to preserve the ruins is now being made by the Belfast Society.

ON September 16, Sir Humphry Rolleston, president of the Royal College of Physicians of London, opened the John Elliott Memorial Pathological and Bacteriological Laboratory at the Chester Royal Infirmary, which has been equipped by public subscription in memory of Dr. John Elliott, honorary physician of the infirmary from 1895 to 1921. Dr. Elliott had a well-furnished laboratory of his own, which he used for the elucidation of his cases, and, in addition to his consulting work, was much interested in radiology and in the treatment of venereal disease. The provision of such laboratories in hospitals in recent years has done much to promote the progress of medicine by bringing together the clinician and the worker in pure science, and the pathological laboratory is now recognised as a necessary part of an efficient hospital.

THE Faraday Society and the British Cold Storage and Ice Association will hold a joint meeting at the Institution of Electrical Engineers on Monday, October 16, to discuss the present position of the generation and utilisation of cold. It will be divided into three sessions, at the first of which laboratory methods of liquefaction and methods of measuring low temperatures will be discussed. The opening address will be delivered by Prof. H. Kamerlingh Onnes, and Dr. Crommelin will give a description of the equipment of the cryogenic laboratory at Leyden. The second and third sessions will be devoted to industrial methods of liquefaction and practical applications of low temperatures. A general introduction will be given by Mr. R. S. Murray of the British Oxygen Company (Limited). M. Claude will deal with the industrial manufacture of hydrogen by the partial liquefaction of water gas, and Mr. E. A. Griffiths with the subject as it touches aeronautical work. Invitations have been extended to members of the London Section of the Society of Chemical Industry and to the Physical Society of London. Others desirous of attending should communicate with the Secretary of the Faraday Society, 10 Essex Street, London, W.C.2.

A PROVISIONAL programme of lectures on meteorology in connexion with the Imperial College of Science and Technology, South Kensington, for the ensuing session is given in the *Meteorological Magazine* for September. There are twenty-one lectures by Capt. D. Brunt on advanced meteorology, dynamical and physical, on Mondays at 3.30 P.M. during the winter and spring terms, beginning on Monday, October 9; seven lectures by Sir Napier Shaw on meteorological conditions of the air-routes of the world, at 3 P.M. on Fridays, commencing on October 13, and continued each week until November 24; three lectures by Mr. R. A. Watson-Watt on wireless telegraphy and weather, at 3 P.M. on Fridays in each of the first three weeks of December; ten lectures on forecasting weather by Sir Napier Shaw on Fridays, at 3 P.M., during the spring term, beginning on Friday, January 19. Discussions on the incidents of the weather charts of the previous week are arranged for on Saturdays at 10 A.M. throughout the year during term-time, beginning on Saturday, October 14.

WE learn from the September number of the *Museums Journal* that Dr. W. Rushton Parker has offered to set aside 100*l.* a year for several years to induce any men excavating in any part of the United Kingdom to look out for fossil remains of any kind, to extract them as completely as possible, and to preserve them until some expert can value them, with the view of presenting them to the National Museums. This is an offer that should be made known to the scientific societies as well as to the museums in various parts of the country.

DR. R. C. FARMER has been invited to take up the position of deputy director of explosives research at the War Office Research Department, and will commence duty in October. Dr. Farmer was formerly chemical adviser to the Explosives Department under Lord Moulton, and was a member of the nitrogen products committee and the chemical committee of the Munitions Inventions Department. Since the armistice he has been a director of Messrs. W. J. Bush and Company, Ltd., chemical manufacturers, of Hackney, London, which position he is now resigning.

A COMMITTEE has been appointed by the Secretary for Mines to undertake research, under the general direction of the Safety in Mines Research Board, into the causes of, and the means of preventing, the ignition of firedamp and coal dust by the firing of permitted explosives. The Committee has been constituted as follows: Sir F. L. Nathan, Mr. W. Rintoul, Dr. G. Rotter, Mr. H. Walker, and Prof. R. V. Wheeler. A grant has been made by the Miners' Welfare Committee out of the Miners' Welfare Fund to meet the cost of initiating the research.

ON account of continued poor health, Dr. George Ellery Hale, director of the Mount Wilson Observatory, has resigned from the Committee on Intellectual Co-operation of the League of Nations. Dr. Robert A. Millikan, director of the Norman Bridge Physical Laboratory of the California Institute of Technology, Pasadena, has been appointed by the council of the league to succeed Dr. Hale.

THE Faraday Medal of the Institution of Electrical Engineers, the first award of which was made by the council in the early part of the year to Mr. Oliver

Heaviside, was personally presented to him by Mr. J. S. Highfield, president of the institution, at Torquay, on September 9.

THE Secretary for Scotland has appointed Dr James Ritchie to be an additional member of the committee appointed to advise him on matters connected with the administration of the Wild Birds Protection Acts.

SIR LAWRENCE WEAVER will shortly relinquish the post of second secretary and director-general of land settlement at the Ministry of Agriculture in order to take up the appointment of director of the Art section and of the Agriculture section of the British Empire Exhibition.

THE Model Abattoir Society, the objects of which are the improvement of methods and conditions in slaughter-houses, has organised an annual Benjamin Ward Richardson lecture in memory of its founder. The memorial lecture, on the sanitarian and humanitarian aspects of Sir Benjamin Ward Richardson's work, will be delivered by Sir William Collins on October 12. Admission is free, and invitations may be obtained from the Rev. George Martin, St. John's Vicarage, Kilburn.

MR. W. K. FORD writes to inform us that an unusually large specimen of the common viper, *Vipera berus*, was caught recently in Epping Forest. The snake, which was a female, is stated to be 29.5 in. in length, the tail measuring 3.12 in. The largest specimen in the British Museum is only a little more than 27 in. in length, though on account of the difficulty of measuring a snake's skin without stretching it—it can be stretched to one and a half times its real length—larger specimens have been recorded. Mr. Ford's specimen appears to be unusually large, but the skin should be submitted for examination to the Zoological Society, Regent's Park, or similar authority, before it can be accepted as a record.

A "WIRELESS WEATHER MANUAL" has been published by the Meteorological Office of the Air Ministry. It is a guide to the reception and interpretation of weather reports and forecasts distributed by wireless telegraphy in Great Britain. A table is given showing the information issued by wireless, revised to June 1, and the instructions are clear and concise for persons who possess wireless receiving sets. It is not only possible to pick up the messages distributed, to aid which the codes used are interpreted, but a "general inference" is given by the Meteorological Office in plain language twice daily, which with a very little intuition can be understood by those little versed in meteorology. A study of the manual will aid in the general understanding of the subject and will render the charting of the information received quite simple. A short list of elementary text-books is given, a study of which will simplify the interpretation of the charts. A weather chart is given daily in many of the newspapers, but the wireless information gives the details much earlier, for it is possible to draw a weather map within about an hour of the observations being made. In the introduction to the manual, it is stated that those wishing to know can find out "what the weather will be in the next twenty-four hours (sometimes longer)."

THE Automatic and Electric Furnaces, Ltd., informs us that the increasing demand for Wild-Barfield electric hardening furnaces has made necessary the removal of the firm to larger works and offices. The address now is: Automatic and Electric Furnaces, Ltd., Elecfurn Works, 173-175 Farringdon Road, London, E.C.1. Demonstration rooms with furnaces in operation will be provided, and suitable arrangements made for hardening large and small parts for firms which desire to compare both the results and costs with those obtained by gas or solid fuel furnaces. Laboratory and industrial electric muffles will also be available for trial purposes.

Our Astronomical Column.

THE ORBIT OF SIRIUS.—This orbit is of peculiar interest from the conspicuous brightness of the primary, from the irregularity in the proper motion having led to a prediction of its duplicity, and from the subsequent verification by the discovery of the companion in 1862. It now presents one of the not very numerous cases in which a complete revolution has been observed. The various determinations of the elements that have recently been published give an index of the degree of accuracy that is attainable. A new determination by Mr. C. P. Howard is given in *Pop. Ast.* (Aug.-Sept. 1922), and that by Mr. R. Jonckheere (Mon. Not. R.A.S., June 1918) is printed for comparison. Both were made by graphical methods, using every refinement possible.

	Howard	Jonckheere
Periastron passage	1894·25	1894·10
Period in years	50·17	50·00
Eccentricity	0·5938	0·60
Semi-axis major	7″·482	7″·55
Inclination	42°·01	43°·4
Node	44°·56	42°·7
Arc from node to periastron	148°·38	145°·6

AN INTERESTING ALGOL VARIABLE.—Mr. A. H. Joy gives a discussion of the Algol Variable, RS Canum Venaticorum, in Publ. Ast. Soc. Pacific, August 1922. It is possible to study the spectra of both components, since the faint star is the larger, and totally eclipses the bright star at principal minimum, when the magnitude is 9.0. The two stars are of equal mass, each 1.3 times the sun; they differ greatly, however, in spectral type, the brighter being F3, the fainter K0. This wide difference is difficult to explain in view of their equal mass. The period is 4.8 days, and the radius of the orbit of each component 5,700,000 miles. The absolute magnitude of the brighter star, deduced from its spectrum, is 2·8, giving a parallax of 0″·008. Three spectrograms have been obtained of the faint star by Mr. Adams; the star is too faint to give satisfactory spectrograms, but it is stated that, taken by themselves, they would indicate a dwarf star. However, from its large size, indicated by the duration of totality being two or three hours, and consequent low density, there can be little doubt that it is really a giant; its absolute magnitude, about 4·2, is very low for a K giant. Altogether the star is rather a puzzling one, and merits careful study.

Research Items.

THE OLDEST DATED SEAL CYLINDERS.—M. Leon Legrain, in the March issue of the *Museum Journal*, claims for the University Museum, Philadelphia, the possession of the oldest-dated cylinder seal, brought from Baghdad in 1800, which belonged to Basha-Enzu, probably the first king of the IVth Kish dynasty, about 2990 B.C. It therefore antedates the famous buffalo seal of Sargani of Akkad, and pushes back toward the third millennium B.C. a standard of art formerly known as the Gudea style. The engraving is of special interest from the point of view of Babylonian ritual. The museum also prides itself on possessing the oldest Cassite royal seal cylinder so far known, bearing the earliest contemporary record of the war god Shugamuna. It is inscribed with the name of the son of King Karaindash, and may be dated about 1540 B.C.

HONEY THAT DROVE MEN MAD.—In the September issue of *Discovery*, Prof. W. R. Halliday, with the help of his colleague, Prof. McLean Thompson, has cleared up a difficulty unsolved by editors of Xenophon's "Anabasis." The historian describes how the retreating Greeks, when they arrived near Trebizond, ate some honey, with effects ranging from intoxication to insensibility. Some authorities have denied that poisonous honey was found in Pontus, but the writers now point out that there is no evidence to show that the breed of bees in Pontus, or the general climatic condition, was responsible for this poisonous honey. When honey is produced in excess, and the floral parts fail to develop, there results an accumulation of by-products in which toxins abound. When the competition for nectar pollen is intense many insects develop a biting habit, piercing the tissues of plants in search of short-cuts to food supply, and this habit results in the formation of poisoned honey. The observation of Pliny that honey was poisonous in some seasons and not in others is thus proved to be accurate, and can be explained on scientific grounds.

THE ROCKS OF MOUNT EVEREST.—In the *Geographical Journal* for September, Dr. A. M. Heron has a note on a small collection of rock specimens made at heights between 23,000 ft. and 27,000 ft. by the climbers on the recent expedition. These specimens show Mount Everest to be a pile of altered sedimentary rocks—shales and limestones—converted into banded hornfels, finely foliated calc-silicate schists, and crystalline limestones. They confirm the views reached by Dr. Heron last year by examination of moraine material from the northern spurs, and by inspection of the mountain by telescope from the Rongbuk valley. From 21,000 ft. to 27,000 ft., Mount Everest appears to be built of these dark hornfels and schists, with occasional bands of white limestone and veins of quartz and muscovite granite. From 27,000 to 27,500 ft. extends an almost horizontal belt of schorl muscovite granite, above which are black schists. Dr. Heron thinks that the age of the rocks may perhaps be assumed, for the present, to be Jurassic or Trias.

WIND-SPEED FROM SEA AND LAND.—The Meteorological Office has issued, as Professional Notes No. 28, a comparison of the anemometer records for Shoeburyness and the Maplin lighthouse, by Messrs. N. K. Johnson and S. N. Sen. The wind-speed in each case is recorded by a Dines pressure tube anemometer. For wind direction Shoeburyness has been used throughout, the Maplin direction recorder being out of order. The wind-speed observations are only available for about ten months in 1919, no observations being to hand from Maplin for the comparison from June 12 to September 1. Maplin lighthouse is five miles from the coast, and is situated twelve miles east-north-east of Shoeburyness. The head of the anemometer at Shoeburyness is carried above the top of a steel girder tower to a height of sixty feet above the surrounding buildings and ninety feet above ground, but there is an avenue of trees about seventy feet high running parallel to the coast at a distance of 150 yards on the landward side of the anemometer. At Maplin the head of the anemometer is about five feet above the apex of the roof of the lighthouse, on the western side, being fifty feet above sea-level. Shoeburyness is said to have a slight predominance of light winds, and at Maplin lighthouse strong winds are decidedly more frequent; the latter is explained by the suggestion that the increased friction over land as compared with the sea causes the air to pile up over the land. This difference of pressure, it is said, must tend to reduce the speed of the surface wind as it approaches the shore-line. There is good evidence of the land and sea-breeze. The height of the head of the anemometer at Maplin seems scarcely sufficient to insure that it is clear from an upward rush of air caused by the obstruction of the lighthouse.

METALLURGICAL RESEARCH.—Volume 16 of the Collected Researches of the National Physical Laboratory has recently been published. It is predominantly of a metallurgical character, although certain papers dealing with engineering subjects are contained therein. The twenty-one papers which it contains are all reprints of papers published by members of the staff in various scientific and technological journals during the years 1919 and 1920. Fourteen of the papers are definitely metallurgical, and a considerable number of these relate to aluminium and its alloys, which have been intensively studied during the last few years, under the general superintendence of Dr. Rosenhain, the head of the department. These investigations are of a very valuable nature, and have contributed in no small degree to the continually extending use of aluminium alloys, not only in aviation, but also in general engineering. Of the papers dealing with iron, attention may be directed to that published by Dr. and Mrs. Hanson on the constitution of nickel iron alloys. The investigations of these authors on this series of alloys have finally enabled the general nature of the equilibrium diagram to be settled once and for all, although they are careful to point out that no very high degree of accuracy can well be claimed. It is interesting to notice that the general result of their researches is to establish firmly the late M. Osmond's hypothesis of the constitution of these alloys, particularly in the range from 0-30 per cent. of nickel. The importance of keeping down the impurities to a minimum is clearly seen in this work, otherwise a true equilibrium is not established. Attention may also be directed to the paper by Dr. Haughton on the study of thermal E.M.F. as an aid in the investigation of the constitution of alloy systems and on the measurement of the electrical conductivity of metals and alloys at high temperatures. The volume contains a paper of the first importance by Dr. Stanton, D. Marshall, and C. N. Bryant on the conditions at the boundary of a fluid in turbulent motion, and two papers by Mr. Baker, the superintendent of the William Froude National Tank. The high character of the series is well maintained in the present volume.

The Inheritance of Size.[1]

THE study of size-inheritance is beset with difficulties which do not attend the study of qualitative differences involving colour and form. Students of genetics have stated size-inheritance in various plants and animals in terms of multiple size factors segregating independently in the Mendelian fashion, but the universal presence of fluctuations which obscure the quantitative effects of separate factors, as well as other difficulties, have prevented the study of size factors being in the same satisfactory condition as that of the factors which control sharply marked qualitative characters.

Stature in man has been investigated from the time of Quetelet and Galton to the recent paper of Davenport,[2] but investigators are not yet agreed even concerning the nature of the Mendelian units, if such they be, which affect and control this feature of bodily measurement. Are there only general growth factors, or are there also separate factors influencing the length of individual segments of the body, such as the legs, trunk, and neck? Davenport concludes that both types of factors are present, and that some races and families have different relative lengths of these segments because of the independent inheritance of such local factors controlling the length of individual bones or segments. Moreover, Davenport believes that crossing between races leads to various bodily disharmonies, such as large teeth in small jaws or a small heart in a large body.

Castle, in a recent study of size-inheritance in rabbits,[3] criticises Davenport's view of local size factors as essentially preformationist, and shows with considerable success that, so far as the rabbits of his breeding experiments are concerned, general inherited growth factors appear to control the size reached by all parts. In crosses between the large Flemish rabbit and small varieties such as the Polish and Himalayan, Castle concludes, as Punnett and Bailey[4] had concluded from earlier experiments on *weight* in rabbits, that several size factors are involved, as indicated by the greater range of variation in F_2 and later generations than in F_1. This substantiates other results of these authors[5] with poultry. They crossed Gold-pencilled Hamburghs and Silver Seabright Bantams and obtained in F_2 and F_3 both larger and smaller birds than the original parental types. That several independent factors are concerned in the determination of size or weight in birds and mammals seems then well established.

But another difficulty comes in to obscure such quantitative results, and that is the fact of hybrid vigour or heterosis, which occurs largely or entirely in the F_1 generation, producing a general increase in the size of the F_1 offspring. For example, in the rabbit crosses, the F_1 is nearer the size of the larger parent owing to this effect, but the effect disappears in the F_2 and later generations. This of course shifts the curve of size temporarily towards the right.

Castle made a careful study of the growth-curves of his rabbits, weighing them at intervals throughout their development to maturity, but he appears not to have studied the variation of his races before crossing. He concludes that the adult Flemish rabbit is larger because it is larger at birth and grows more rapidly and for a longer period than the small Polish rabbit. This is contrary to the views of Punnett and Bailey that age of maturity is not necessarily closely correlated with size. Castle applies his results to man, and reasons that natives of the south of Italy are short of stature and short-limbed because they cease to grow at a relatively early age, while Swedes and Scotch are tall and long-limbed because they mature later.

In the hybrid rabbits, series of measurements were made of weight, ear-length, skull dimensions, and certain leg bones. From these data the correlation-coefficients between the various measurements were determined and were found to be uniformly high. Thus the correlation between ear-length and weight in F_1 and F_2 rabbits was 0·836, and between lengths of femur and skull 0·871. This furnishes strong support for the conclusion that the size of all parts is determined by general growth factors affecting the whole body, and not by independently segregating factors affecting the size of particular organs. Davenport points out that certain races of man have long legs and relatively short trunks, while others have short legs and longer trunks, but Castle holds that the former races are absolutely taller, and regards them as a later growth stage than the short races. Whether this explanation will apply to all races of man remains to be seen. The most urgent requirement at the present time is a mass of accurate anthropometric measurements of all parts of the body in various races.

Many genetic factors are known to affect chiefly one organ of the body, such as the eye or the wing in flies, and since that is the case there seems no *a priori* reason why some size factors should not also affect chiefly certain organs. To demonstrate such an effect, however, a considerable mass of biometric data is required. So far as plants are concerned, the results of Gates[6] show that size factors in hybrids are in some cases local in their effects. In crossing species of Œnothera having large and small flowers respectively, he obtained in F_2 and later generations frequently a wide range of flower-size on the same plant, and in many cases even the four petals of the same flower differed widely in length. Thus it is clear that local size factors occur in plants. Whether they also occur in animals and man remains to be determined.

That an increase in the range of variation of the F_2 as compared with the F_1 is not in itself sufficient to prove the presence of several inherited size-factors, is indicated by a recent paper of Sumner and Huestis.[7] In connexion with extensive breeding investigations of the California deer-mouse, *Peromyscus maniculatus*, they have compared the length or weight of corresponding right and left bones such as the mandible and femur. In this way they obtained sinistro-dextral ratios for these bones and showed statistically that there is no inheritance of such a ratio from one generation to the next, *e.g.* if the parents had a slightly longer left femur there is no tendency for the same condition to be repeated in the offspring. Nevertheless, they found that in crosses between different sub-species these ratios showed greater variability in F_2 than in F_1. This fact will need to be taken into account in future studies of size-variation.

An Optical Sonometer.

ONE form of an optical sonometer recently made by Messrs. Adam Hilger, Ltd. (of 75A Camden Road, N.W. 1), is shown diagrammatically in Fig. 1. The

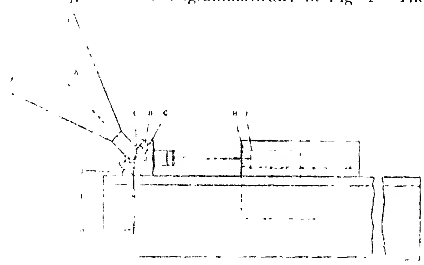

FIG. 1.

apparatus is designed to record the pressure variation caused by sound waves. It consists of a diaphragm box B, to which is attached a horn for receiving sound waves. In box B is a diaphragm with a platinised, silvered, or gilt inner face; this is the actual receiver. Recording the vibrations produced in the disc is accomplished by means of a beam of light directed from the source D (a Pointolite Lamp of 30 or 100 candle-power) by a condenser E through the slit F and brought to a focus on the diaphragm C. Thence by means of lenses G and H an image of the slit is formed on the photographic paper or film on the drum J. The lens H being cylindrical with its axis parallel to the drum, the beam of light is brought to an intense point image on the drum, and as the latter rotates a record of the deflection of the diaphragm is obtained. The spot of light can be focussed on the drum at any distance from 4 to 20 inches according to the amplitude of vibration under investigation and the degree of magnification consequently required.

Some of the models constructed are fitted with a camera into which the film is loaded through a small aperture at the back, while an arrangement for visual observation of the sound wave is also included. The revolving drum, on which the record of the vibrations is made, is enclosed in a specially designed camera with an automatic shutter; by this means any fraction of the drum, from one-sixth to one complete revolution, can be exposed according to the type of record which it is desired to make.

Records of various sounds have been made with the apparatus, e.g. for whistling at a frequency of about 1300 per second, singing at about 200 per second, and of the sound produced by a leather-covered mallet on wood. This last is shown in Fig. 2, the frequency being about 250 per second.

FIG. 2.

The Rowett Research Institute, Aberdeen.

THE Rowett Institute, which was formally opened by Her Majesty the Queen on September 12, had its origin in the scheme of research in agriculture adopted by the Development Commission in 1911. Under that scheme provision was made for the establishment of one or more Institutes to carry out research in each of the branches of agricultural science. It was decided to establish two Institutes for the study of Animal Nutrition, one at Cambridge and one in Scotland. In 1913 a Joint Committee representing the University of Aberdeen and the North of Scotland College of Agriculture was constituted to act as a governing body for the Scottish Institute. Preliminary work was begun in 1914, but was stopped by the war. In 1920 the scheme for the development of the Institute was approved by the Board of Agriculture for Scotland and the Development Commission, and the erection of the buildings began early in 1921. The buildings are now practically completed, except for the fitting up of one or two of the laboratories.

In determining the nature of the Institute to be established it was recognised that the basis of practical experimental work is the researches of the purely scientific worker. Provision was therefore made for work in those branches of science that constitute animal nutrition. The Institute was planned to consist of the following departments: physiology, biochemistry, bacteriology, and pathology, which are housed in the one main building, and animal husbandry, which consists of an experimental stock farm with buildings adapted for conducting feeding experiments. To facilitate the collaboration of those engaged in laboratory researches and those carrying out feeding experiments, the main building containing the laboratories has been erected on the experimental farm. This enables the workers to be in daily contact with each other, and to be conversant with the different aspects of the problem or group of problems on which the Institute is engaged.

The experimental farm is situated on the outskirts of Aberdeen, within easy access of tramway and train. The building containing the laboratories is built of granite and is 156 feet long by 15 feet deep in the central block and 30 feet deep in the wings. It consists of two floors and a basement. The biochemical department, the calorimetry room, the aseptic room, and certain other rooms occupy the ground floor. The physiology and the bacteriology and pathology departments are on the first floor. In the west wing of this floor is the administrative department, rooms for filing records and statistics, and the library. About 30 yards west of this building are the experimental farm buildings which have a floor area of about 1500 square yards. The part nearest to the building containing the laboratories is occupied by two rooms, where animals under metabolic experiment can be kept in cages. The rest of the building consists of food stores, food preparation rooms, and stalls and pens for the

accommodation of farm animals under feeding experiments.

The capital outlay, which was estimated in 1920 at 40,000l. to 50,000l., will amount to about 46,000l. Of this sum the Treasury, on the recommendation of the Development Commission, provided 20,000l. Mr. John Quiller Rowett, LL.D., generously contributed 10,000l., and in addition supplied sufficient funds to purchase the experimental farm. Various smaller sums have been received from other contributors, but the whole of the necessary funds have not yet been raised.

The Queen, at the opening ceremony, visited all the departments and talked with the senior workers, asking questions that showed a deep interest in the research work in progress. She was especially interested in the work on indirect calorimetry, and asked to be shown all the apparatus and to have the method explained. In the experimental farm she was chiefly attracted by the dairy cows. These are Ayrshires, a breed kept at the Balmoral Estate. She asked questions about the breed and also about milk production in general which showed an interest in and an appreciation of the importance of the dairy industry.

After the visit to the different departments the Queen proceeded to the library, where there was a company of about 120, including the Duchess of Atholl, the Duke of Richmond and Gordon, the Marquis and Marchioness of Aberdeen, the Marquis and Marchioness of Huntly, and representatives of public bodies. Here she was presented with a gold key by Dr. Rowett, and formally declared the Institute open. She signed the visitors' book, and before leaving planted a tree in the grounds of the Institute to commemorate the visit.

The Sun's Activity, 1890-1920.

THE sun, as is well known, is a variable star having a period of approximately eleven years, but, unlike other stars, its variability can be determined from several different visible phenomena and not solely from the total integrated light emitted. As classed among stars, it is not considered, however, as a regular variable, because the approximate period of eleven years is itself made variable through other minor periods of various lengths.

Though the sun has a dominating action on many terrestrial phenomena, authorities differ as to the exact relation between the pulsations of the two bodies. It is important, therefore, always to keep in mind, so far as possible, the actual state of solar activity at the moment, *i.e.* whether the sun is in a quiescent state through lack of spots and prominences, or whether it is in a very turbulent condition caused by their abundance.

The data for determining the state of the activity of the sun are published separately year by year in various volumes from different sources, and are only brought together, probably with some difficulty, by research workers who wish to use them for particular inquiries.

Dr. W. J. S. Lockyer has recently co-ordinated the solar data regarding the sunspotted area, the latitudes of the activity zones of sunspots and prominences, together with the variations in the form of the corona for the period 1920 *to as near the present as possible*. The accompanying diagram (Fig. 1) illustrates the solar changes in graphic form. The following paragraphs deal briefly with each set of curves individually, including the sources of the data.

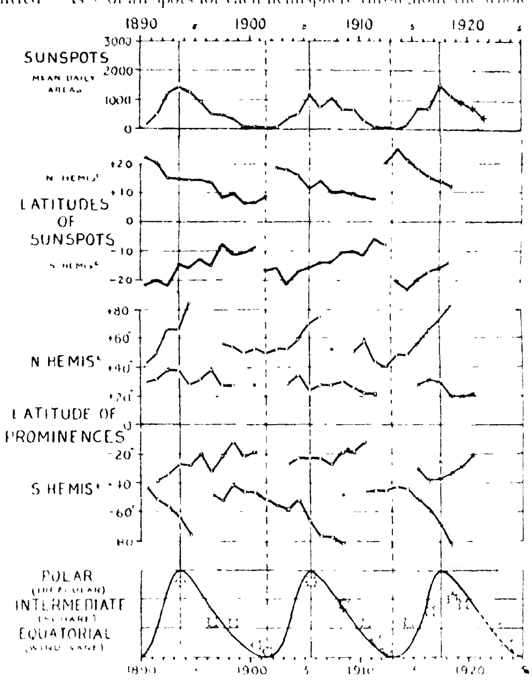

FIG. 1.

MEAN DAILY AREAS OF SUNSPOTS.—Each of the points in the curve represents the mean of the daily areas of sunspots corrected for foreshortening for each year. The values are published by the Astronomer Royal yearly in the Monthly Notices of the Royal Astronomical Society, the last value published being that for 1918 (vol. 82, p. 485). The three later years marked with crosses are only provisional values.

It will be seen that the maximum spot activity occurred in the years 1893, 1905, and 1917, while the years of minimum were 1901 and 1913. The next minimum will probably fall in 1924 or 1925.

LATITUDES OF SUNSPOTS.—Under this heading there are two sets of curves, one for the northern and the other for the southern hemisphere of the sun. Each point represents the mean heliographic latitude of all spots for each hemisphere throughout the whole year. The data are taken from the same sources as mentioned above. It will be noticed that a new sunspot cycle is always heralded by outbursts of spots in zones of high latitudes (about 22°), while the zone of spots nearer the equator is dying out.

LATITUDES OF PROMINENCES.—Here also there are two sets of curves, one for each hemisphere, where in the case of the spots there was only one zone for

each hemisphere, for prominences there are two zones Each point in the curves represents the mean latitude of each zone throughout the year It will be noticed that in each hemisphere the zone in lower latitudes gradually approaches the equator, dying out just before or at sunspot minimum, while the zone further away from the equator increases its latitude rapidly and dies out at or a little after sunspot maximum The data up to 1914 are published in the Memoirs of the Kodaikanal Observatory (vol. 1, part ii) by Mr John Evershed, and the remainder have been extracted from that Observatory's Bulletins published half yearly, from which the mean yearly latitudes of the zones have been provisionally determined by Dr Lockyer

THE FORMS OF THE CORONA.—The last curve shows the condition of activity of the sun as indicated by the form which the corona takes when seen at total eclipses

When the corona (polar form) exhibits streamers all around the solar disc, *i.e.* in all solar latitudes, this indicates a very turbulent state of the solar atmosphere and a time therefore of maximum activity At this time the prominences reach their highest latitudes When the streamers are confined to the equatorial regions and the poles are quite clear and void of streamers, the corona takes an "equatorial" or "wind-vane" form, and the solar activity is at a minimum Intermediate stages are indicated by the corona taking an "intermediate" or "square" shape The various forms of the corona are indicated clearly in the curve by three different symbols The curve also shows the forms expected in the two approaching eclipses, namely, of this and of next year The form for the present year will be of the "intermediate" type, while that for 1923 should be typical of the "equatorial" type The data for the various forms of the corona have to be obtained from the individual reports of eclipse expeditions, but those to which reference has here been made have been collected by Dr Lockyer and published in the Monthly Notices of the Royal Astronomical Society (vol 82, p 320)

All the solar phenomena described above thus indicate clearly that the activity of the sun is decidedly on the wane, and that the epoch of minimum disturbance in the solar atmosphere is approaching and will be reached in the year 1924 or 1925

University and Educational Intelligence.

BRISTOL The degree of Ph.D has been awarded to Mr Joseph Fincham for his dissertation on "The Concept of Activity"

LONDON.—The list of courses of University Extension Lectures for the session 1922-23 has recently been issued, containing particulars of some 90 courses and lectures which will be given in the University and locally Of this number, 14 only are on scientific topics Dr W B Brierley is giving a course of 24 lectures at Gresham College on inter-racial problems of man, and a similar course at Morley College on the principles of evolutionary biology, F Womack is giving 2 lectures on wireless telephony at Hatch End and at Hounslow, and 5 lectures on pioneers of science at Wood Green, and F J Chittenden, 3 lectures on horticulture at Hatch End The remaining science lectures are related to psychology Miss V H Hazlitt, 10 lectures on the psychology of character and conduct, at Croydon, Mr Cyril Burt, 5 lectures on psycho-analysis, at Twickenham, S E Hooper, 24 lectures on psychology, at Wimbledon and also at Wood Green; and F O Lewis, 24 lectures on psychology, at the Working Men's College, Crowndale Road, N.W. There are also four psychology courses, at Croydon, at the Mary Ward Settlement at Tavistock Place, W.C., at Wandsworth, and at Wood Green, for which lecturers' names are not yet given Further particulars of the lectures can be obtained from the local secretaries whose addresses are given in the lecture list, application for which should be made to the Registrar, University Extension Board, University of London, South Kensington, S.W.7

THE *Chemiker Zeitung* of August 29 reports that Dr. H Lecher, of the University of Munich, has been appointed professor of organic chemistry at the University of Freiburg.

A SPECIAL committee of the World's Student Christian Federation has been appointed to co-operate with the Universities' Library for Central Europe in its work of securing British books, journals, and scientific papers for the universities of Central Europe Donations of books, periodicals, and money should be forwarded to Mr B M Headicar, Universities' Library and Student Relief for Europe, London School of Economics, Houghton Street, W.C.2

ON several occasions recently the *Chemiker Zeitung* has reported the gifts of large sums granted by industrial concerns to universities and to associations of students, for the assistance of these bodies in teaching scientific subjects, particularly chemistry Although the amounts, which run into millions of marks in individual grants, may seem modest when translated into English currency, they represent important contributions in Germany, and the attention of British manufacturers might well be invited to the matter It is evident that Germany realises, as she did in former years after defeat, that the hope of the future lies in education, and one cannot help feeling that the victors in the recent war would do well to consider whether their future also does not lie in the same direction, and do a little more of a practical character in the furthering of the work of our educational institutions The reduced grants made to the universities will be reflected in reduced facilities, and if the industries which have reaped so much benefit from research in pure science made in the universities, often associated with individual hardship on the part of the students, were to make some return, it would be repaid to them a hundred-fold.

THE draft Regulations for Secondary Schools recently issued by the Board of Education remedy the anomalous position which hitherto geography has occupied in advanced courses As a school subject, geography has steadily gained ground, and in 1921 was offered by no less than 78 per cent of the candidates taking the School Leaving Examination Furthermore, Sir Richard Gregory, in his presidential address to the Education Section of the British Association this year at Hull, pointed out the still greater part this subject could, and should, play in economy of time-table and efficiency of teaching At the other end of the scale, the Universities have steadily increased the facilities for graduation in geography There remained, however, the hiatus of the advanced courses which cut off, in large measure, the supply of students of geography The 1922 Regulations provide for a new group of studies, E, which is defined as "Geography, combined with two other subjects approved by the Board, of which one must be History or a Science." The way is now clear for a complete revision of the syllabuses in geography for the Higher School Certificate and for the provision of university scholarships in this subject.

Calendar of Industrial Pioneers.

October 1, 1838. Charles Tennant died.—The founder in 1797 of famous chemical works at St Rollox, Glasgow, Tennant while manager of a bleaching field near Paisley discovered a method of controlling chlorine gas by the admixture of lime. He introduced the manufacture of chloride of lime in a solid state, to which he gave the name bleaching powder. His production of bleaching powder in 1799–1800 was 52 tons, the price being 140*l.* per ton. By 1835 the St. Rollox works had become the most important chemical works in the world.

October 2, 1804. Nicolas Joseph Cugnot died.—A military engineer and the author in 1766 of "Éléments de l'art militaire ancien et moderne," Cugnot in 1769 made the first steam-propelled road carriage, and two years later built a steam tractor for the French Government for hauling artillery. This vehicle was to carry a load of 4½ tons at 2¼ miles per hour. Though never used, this carriage is preserved in the Conservatoire des Arts et Métiers.

October 3, 1867. Elias Howe died. One of the chief pioneers of the sewing machine, Howe was the son of a farmer of Spencer, Massachusetts, and was born in 1819. He began work on the sewing machine in 1841, took out a patent in 1846, and was one of the first inventors to place the eye of the needle towards the point.

October 4, 1821. John Rennie died.—Acknowledged as the greatest civil engineer of his day, Rennie was the builder of the London Docks, the East India Docks, the Plymouth Breakwater, Waterloo and Southwark Bridges, and he prepared designs for London Bridge. He was born at Phantassie, East Lothian, in 1761, gained practical experience under Andrew Meikle, attended the lectures of Robison and Black, and in 1784 erected the Albion Mills for Boulton & Watt, in London, the site of which was afterwards occupied by Rennie's workshops. He is buried in St. Paul's Cathedral.

October 5, 1892. Alexander Carnegie Kirk died. The author of many improvements in marine engineering, Kirk, after gaining experience at Maudslay's and at Elder's, became a partner in 1877 in the firm of Napier. He was especially known for his advocacy of high steam pressure and the triple-expansion engine, the advantages of which were demonstrated in the s.s. *Aberdeen* built by him in 1882, which on a voyage to Australia showed a saving of 500 tons of coal.

October 6, 1905. Charles Brown died.—Brown has been called the founder of mechanical industry in Switzerland. Brought up in London, in 1851 at the age of 24 he entered the service of Sulzer Brothers, a firm of mechanical engineers at Winterthur. He established afterwards the Swiss locomotive works at Winterthur and also played a prominent part in the creation of the Swiss electrical industry.

October 7, 1908. Jean Baptiste Gustave Adolphe Canet died. A distinguished armament engineer, Canet was trained at the École Centrale des Arts et Manufactures, fought in the Franco-German War, and for a time engaged in railway engineering. From 1872 to 1881 he was associated with Vavasseur at the London Ordnance Works, and in 1876 brought forward his theory of hydraulic brakes for checking the recoil of guns. Returning to France he became the head of armament works at Havre and after the amalgamation of these works with those of Schneider at Creusot became manager.

Societies and Academies.

SWANSEA.

Institute of Metals, September 20.—G. D. **Bengough** and J. M. **Stuart**: The nature of corrosive action, and the function of colloids in corrosion (Sixth Report to the Corrosion Research Committee of the Institute).—Sir Henry **Fowler**: The effect of superheated steam on non-ferrous metals used in locomotives. Superheated steam as used on locomotives generally leaves the superheater at a temperature of 340° C. On the Midland Railway, piston tail rod bushes were made of M.R. A1 alloy (copper, 87; tin, 9; zinc, 2; lead, 2). A phosphor bronze (copper, 88; tin, 11; phosphorus, 1) has been found satisfactory. For piston rod packing, McNamee rings (copper, 75.5; tin, 8.5; zinc, 0.33; phosphorus, trace; nickel, 0.5; lead, 15.0) are used satisfactorily. These rings prevent the steam coming into contact with the white metal (lead, 70; antimony, 30) packing rings. With the temperature rising to 425° C. the packing rings may fuse. Piston valve fittings and cylinder relief valves are made of alloy M.R. A1. For by-pass valves which are subjected to shock, a nickel-brass gave good service, but was replaced for economy by malleable iron or steel castings.—A. H. **Mundey**, C. C. **Bissett**, and J. **Cartland**: White metals. The manufacture and use of white metal for industrial purposes is described, and constitution and microstructure are dealt with only so far as the uses and manufacture are concerned. Antifriction or bearing metal, printing alloys, die-casting alloys, metals for chemical works castings, solders are discussed.—J. H. **Andrew** and R. **Higgins**: Grain size and diffusion. Diffusion at high temperatures may take place simultaneously with grain-growth, while at low temperatures it promotes a breakdown in the grain-size. These results have been applied to the annealing treatment of castings. It has been assumed that in the interior of the crystalline grains the system of closest packing holds, while at the boundaries the atoms in the separate grains touch only at one part of the circumference. This explains the decrease in specific gravity with an increase in the number of grains, for in such an arrangement free spaces occur. Plastic deformation, by shifting some of the atoms from their positions of equilibrium, will cause them to rearrange themselves when heated to a sufficiently high temperature. This rearrangement will be such that the stressed atoms will fall in, row for row, with the unstrained atoms of the adjacent crystal. This effects a gradual migration of the grain boundary which, proceeding from every side of a crystalline unit, may result in one grain being divided up and absorbed by others. The final bounding surface will result when the boundary configuration is reached.

PARIS.

Academy of Sciences, August 28.—M. L. Maquenne in the chair.—L. **Mangin** and N. **Patouillard**: The destruction of the woodwork at the château of Versailles by *Phellinus cryptarum*. A detailed examination of the oak beams showed a varied fauna and flora, but *Phellinus cryptarum* is mainly responsible for the damage. This fungus has not hitherto been regarded as destructive to wood.—Jacques **Chokhate**: The development of the integral $\int_a^b \frac{f(y)}{x-y}\,dy$ as a continued fraction.—Ch. N. **Moore**: The equivalence of the methods of summation of Cesàro and of Holder for multiple limits.—Nilos **Sakellariou**: Polar systems.—Amédée **Béjot**: Placing in reciprocal

perspective, figures of the same species.—M. **Gignoux** and P. **Fallot**: The marine quaternary on the Mediterranean coasts of Spain.—Raoul **Combes** and Denise **Kohler**: The rôle of respiration in the diminution of the carbohydrates in leaves during the autumnal yellowing. It has been commonly held that during the change of colour of leaves in the autumn, the carbohydrates are withdrawn from the leaf and stored in the plant as reserves. It has been proved by Michel Durand that some of the carbohydrates are removed by rain, and in the present communication proof is given that part is used up by respiration and leaves as carbon dioxide.—J. **Carrère**: The sphincter of the iris in the selacians. This muscle in the selacians, especially in species possessing a pupil-shaped opening, is more developed at the nasal and temporal extremities of the pupil; it is less important, and may even disappear, in the ventral and dorsal sectors.—Paul **Wintrebert**: The mechanical polarity of the germ of selacians (*Scyllorhinus canicula*) at the time of gastrulation.

September 4.—M. L. Guignard in the chair.—Théodore **Varopoulos**: A theorem of M. Rémoundos.—Alf **Guldberg**: The theorem of M. Tchebycheff.—Victor **Henri** and Pierre **Steiner**: Absorption of the ultra-violet rays by naphthalene. From a quantitative study of the absorption of solutions in hexane, ether, alcohol, and water, seventeen bands have been found between wave-lengths 3207Å and 2503Å. These results are compared with those previously obtained for benzene by a similar method.—Erik **Hulthén** and Ernst **Bengtsson**: Researches on the band spectra of cadmium.—G. **Murgoci**: The classification of the blue amphiboles and of certain hornblendes.—Marcel **Mirande**: The formation of anthocyanin under the influence of light on the scales of the bulbs of certain lilies.—Raphael **Dubois**: The destruction of mosquitoes by eels. Goldfish have been suggested for destruction of mosquitoes as they eat the larva, but they have the disadvantages of being costly and requiring a pure and well aerated water. Young eels in the spring are equally voracious and devour the larvæ readily. They are more readily procurable than goldfish, and live equally well in fresh and salt water, and even in water containing sewage effluent.

SYDNEY.

Royal Society of New South Wales, August 2.—Mr. C. A. Sussmilch, president, in the chair.—C. E. **Fawsitt** and C. H. **Fischer**: The miscibility test for eucalyptus oils. Instead of testing the solubility by measuring the volume of aqueous alcohol required to obtain complete solution of a measured volume of oil, the critical solution temperatures with definite mixtures of alcohol and water are taken after the manner of testing fixed oils. This method is more sensitive for the indication of small changes in composition of the oil. The critical solution temperature in some cases varies markedly with time and as the oil is kept.—R. T. **Baker** and H. G. **Smith**: The Melaleucas and their essential oils, Pt. VI. Two species are discussed, *Melaleuca ericifolia*, Sm., and *M. Deanei*, F. v. M. Oil was first distilled from *M. ericifolia* by Mr. J. Bosisto in 1862, and Dr. J. H. Gladstone in 1864 determined its physical constants. The chief oxygenated constituent was thought to correspond with that in ordinary oil of "cajuput." The yield of oil obtained by the present authors was 0·8 per cent., and the chief oxygenated constituent found to be dextrorotatory terpineol, while less than 10 per cent. of cineol was present. Pinene, limonene, and a sesquiterpene were also detected. The yield of oil from young material of *M. Deanei* was also 0·8 per cent., and consisted almost entirely of pinene with about 15 per cent. of cineol. Old leaves of this species contain very little oil.—A. R. **Penfold**: The essential oil from *Backhousia myrtifolia*, Pt. I. This small tree inhabits gullies containing running water in the coast and coast mountain districts of New South Wales. Material collected at Lane Cove near Sydney, and at Currowan of the southern district, yielded 0·3–0·75 per cent. of a brown-yellow oil, varying with the time of year and locality. The oil possesses a pleasant odour and is heavier than water. Its principal constituent is elemicin (80 per cent.), a somewhat rarely occurring phenol ether. The remainder of the oil consists of α-pinene, unidentified alcoholic bodies and phenols, sesquiterpene, and a paraffin of melting point 62°–63° C.

CAPE TOWN.

Royal Society of South Africa, August 16.—Dr. J. D. F. Gilchrist, president, in the chair.—W. A. **Jolly**: The rhythm of discharge of the spinal centres in the frog. The rate of discharge of the cord in Xenopus at different temperatures, as indicated by galvanometric records from the gastrocnemius muscle reflexly excited, was discussed.—J. P. **Dalton**: On the mathematics of the homogeneous balanced action. It has been shown by the author that the integrated velocity equations of chemical reactions can be written in terms of a certain function. The same function may be employed in the treatment of the homogeneous balanced action.

Broadcasting in Great Britain.

THE Postmaster-General has, it is announced, decided temporarily to suspend the issue of licences for the reception of wireless telegraphy and telephony except to those engaged upon experimental work. In an official statement sent out by the Post Office in relation to the broadcasting situation, it is explained that the Postmaster-General has been prompted to adopt the course he has taken in connexion with the issue of licences for reception purposes owing to the fact that there has been a divergence of views concerning the details with regard to the constitution of the company which it is proposed to form for the purpose of providing the broadcasting services. Not only have the proposed articles of association of the proposed broadcasting company proved unacceptable, as a whole, to the Postmaster-General and his advisers, but also, it would appear, that differences on essential points have also been manifest between the members of the committee dealing with the Postmaster-General in this matter. Considerable progress has, it is stated, now been made towards the solution of the differences between the members of the committee in question, and, at a conference held at the Post Office on September 12, an agreement was reached as to the conditions under which the Postmaster-General will issue the necessary licences for the erection of the broadcasting stations; it therefore now only remains for the Post Office officials and the committee representing the proposed company to settle certain details.

In the official statement in question it is announced that the Postmaster-General and the committee both desire it to be known that membership of the proposed broadcasting company will not, of itself, entitle a member to use the patents of other members in the manufacture of receiving apparatus. The manner in which the broadcasting situation is being handled by the Post Office has, in some quarters, caused considerable disquietude; the policy which is being pursued by the Postmaster-General whereby an attempt is to be made to control the broadcasting situation by and through the means of the proposed articles of association of the company which it is proposed to license to provide the broadcasting services, certainly seems to be one of doubtful wisdom. As the provisions to be included in the proposed articles of association at the instance or with the approval of the Postmaster-General have not yet been made public, it would be premature further to discuss the matter at the moment.

A point of considerable importance which requires

early attention, is the attitude the Post Office is taking in connexion with the issue of licences for experimental work. In the official statement, to which reference has already been made, it is indicated that the Postmaster-General intends in future to issue licences for experimental stations alone to those who can satisfy him that they have a sufficient knowledge of the subject to enable them to make a proper use of such licences. It is surmised in some quarters that this departmental rule has been framed with the view of restricting the grant of licences for experimental work alone to trained scientific workers. In the interests of the progress of science it is essential that the terms and conditions under which it is possible to obtain a licence for experimental work shall not be made so exacting and stringent as to exclude the amateur from the field of wireless research.

The requirements in relation to the issue of licences for experimental stations are definitely laid down in clause 2 of the Wireless Telegraphy Act, 1904 (4 Ed. 7, c. 24), wherein it is provided that "where the applicant for a licence proves to the satisfaction of the Postmaster-General that the sole object of obtaining the licence is to enable him to conduct experiments in wireless telegraphy, a licence for that purpose shall be granted subject to such special terms conditions and restrictions as the Postmaster-General may think proper, but shall not be subject to any rent or royalty" The language used in this clause is sufficiently clear to show that it cannot have been the intention of the legislature in any way to penalise the amateur experimentalist in connexion with the procuring of a licence for experimental work. In the matter of the grant of such licences the amateur experimentalist and the trained scientific worker have an equal claim upon the Postmaster-General, provided that they can prove to his satisfaction that the station which they desire to equip is an experimental one, in contradistinction to one fitted up for commercial work. The amateur should receive the fullest encouragement and consideration from the Post Office. Mischief will alone result should the steps which the Postmaster-General and his advisers are contemplating with regard to the issue of licences for experimental work have the unfortunate effect of moving amateurs to evade the official regulations and the provisions of the Wireless Telegraphy Act, 1904.

The Problem of Solution.

THE problem of solution has engaged the attention of many men of science from the time of Newton to the present day, and it cannot be said that a complete and all-embracing theory has yet been advanced that will interpret all the observed facts. The subject lends itself admirably to those who concern themselves with pointing out weaknesses of accepted conceptions without replacing these ideas by adequate substitutes.

A contributor, writing under the pseudonym Dr. B. Lagueur, in the *Chemical Age* of September 2, very ably and wittily adopts the style of the "Compleat Angler," and produces an imaginary conversation between a "Chymist" (baptised Henry), in whose chemical philosophy there has not arisen the necessity of adopting the ionic hypothesis, and a "Friend," who, being a creation of the author and therefore fundamentally of similar persuasion, is unable to make a satisfactory case for its adoption.

Of the theories advocated it is now generally recognised that the older conception of hydrate formation is insufficient to account for the experimental results obtained. The hydrone theory of Armstrong appears to be that beloved of the "Chymist," and explains solution by assuming the existence of new molecules formed by the union of the water with the solute. It has a certain measure of experimental support, but, despite this, despite the known complexity of water, and despite the crystal work of Bragg, it embodies a number of assumptions difficult to verify, and by itself is scarcely likely to displace the more firmly established hypothesis of Arrhenius, which, though revolutionary, imperfect, and easily attacked, yet fulfils the functions of a hypothesis, and therefore serves a useful purpose.

The ionic hypothesis has explained many facts hitherto extremely puzzling; it has opened out new lines of research, and "as a working hypothesis gives qualitative and quantitative explanation of a large number of chemical phenomena which can otherwise only be accounted for in a vague and unsatisfactory way." The solvate theory—a combination of the original ionic hypothesis with the hydrate and hydrone conceptions—has been the outcome of a long series of experiments on solution by Jones and his collaborators in America. The ionic hypothesis, shorn of the frills and furbelows given to it by enthusiasts, is generally accepted with certain mental reservations as to the existence of ions, except by those who, as Jones says, "oppose it after a careful study of the facts or are unable or indisposed to adapt themselves to new ideas."

Many hypotheses are at best unstable and transient, but before any are discarded they must be killed, and the death of the theory of electrolytic dissociation is not yet, notwithstanding the thrusts given to it in the article in our contemporary.

The New Way of Thinking Physical Reality.

(1) *The Philosophy of Humanism and of other Subjects.* By Viscount Haldane. Pp. xix+302. (London: J. Murray, 1922.) 12s. net.

(2) *L'Expérience humaine et la causalité physique.* Par Prof. Léon Brunschvicg. (Bibliothèque de Philosophie Contemporaine.) Pp. xvi+625. (Paris: Félix Alcan, 1922.) 30 frs.

(3) *La Notion d'espace.* Par Prof. D. Nys. (Fondation Universitaire de Belgique.) Pp. 446. (Bruxelles: Robert Sand; London: Oxford University Press, 1922.) 15s. net.

(4) *The Evolution of Knowledge.* By George Shann. Pp. vii+100. (London: Longmans, Green and Co., 1922.) 4s. 6d. net.

THE direction which scientific research has taken in the twentieth century is imposing on philosophy a task the magnitude of which is probably not yet realised by any one. Aristotle, in his doctrine of the four causes and in his discovery of the syllogism, the logical instrument which gave that doctrine the appearance of precision, determined the type and the mode to which all succeeding scientific research right up to modern times has adhered. The essential thing in the Aristotelian doctrine is that the analysis of the physical universe proceeds in precisely the same way as the analysis of the elementary conditions which govern the production of a work of art. There is, that is to say, a matter on which an agent impresses a form in order to express an end or purpose. The modern sciences of biology and psychology had already begun to undermine this æsthetic mode of thinking reality and now the Einstein theory in mathematical physics has swept away its foundations. The result is that once more in human history physics and metaphysics are joined together. The union has been brought about by physical science itself, without any betrayal of its positive and experimental character, by fearless acceptance of the apparently paradoxical results of experiments. It is the outcome, we can now see, of a historical progress of pure science in the last three centuries, continuous in its development from Galileo to Clerk Maxwell, Mach and Einstein, which has led to a complete revolution in the way of thinking physical reality.

The philosophical current of human thought, although always a reflection of the scientific current, has not the same rhythm. It happens at times, unexpectedly and as if by a sudden explosion, that the scientific current is interrupted; some wholly unlooked-for results of experimental investigation have occurred, and the human mind has sprung at once to the general principles whence those results proceed. A new vision of truth then opens out before human consciousness involving its whole conception of the universe and mind. It was such a vision which produced the new birth of modern philosophy in the seventeenth century. To-day a new and most startling discovery, following indeed a long historical development but a development we can appreciate only now because the discovery has given us the vantage ground from which to look back on the history, is opening to us a new vision of truth and making us rethink our whole concept of the nature of physical reality.

(1) and (2) It is this new way of thinking physical reality which, each in his own way, the authors we have grouped together are seeking to express. In the case of Lord Haldane's "Humanism" and Prof. Brunschvicg's "L'Expérience humaine" there is full consciousness of it and a direct purpose of exposition. It is noteworthy that two such books, widely different in their method and scope and yet so singularly in agreement, both in their viewpoint and aim, should appear together. Lord Haldane, who is not a mathematician, devotes himself to detailed philosophical analysis of the new mathematical concept, while Prof. Brunschvicg, a mathematician of distinction and known to us chiefly by his *editio princeps* of Pascal's works, traces with an extraordinary grasp of details the historical development of the concept of physical causality which has resulted in the generalised theory of relativity, and both interpret to us the new concept of the physical universe in practically identical terms. The humanism of the one is the human experience of the other, and Lord Haldane's "foundational nature of knowledge" is Prof. Brunschvicg's "philosophie de la pensée."

The cosmology of Einstein differs fundamentally from every previous doctrine inasmuch as it discards both the factors which in the long history of human thought have contended against one another for pre-eminence. It regards neither the definition of the concept, whence deduction is made, nor the datum of experience, on which induction is based, as fundamental. Einstein's world is a world of figures, supposing neither *a priori* concepts nor sensible images. These figures, however, are not fictions, they are not even abstractions, they correspond to coefficients which reality furnishes. Mathematics determines for us the *invariant* which passes from one system to another.

Between Newton and Einstein, Prof. Brunschvicg tells us, there is this difference that according to Newton the thing to be measured has an absolute content, inaccessible it may be directly to man, but certainly accessible to God. That is to say, the Newtonian

universe would be an object of intuition, that is, would form a picture, at least to God. According to Einstein, we cannot say, speaking absolutely, that there is any picture even for God. The picture is only known as a function of the frame. That is, the things measured are only known through the measurings, and the measurings are bound up with the things they serve to measure. The understanding of this reciprocity makes it impossible to separate and consider apart what, for the convenience of language alone, we distinguish as frame and picture. Science goes in a kind of perpetual oscillation, with an ever-narrowing adaptation, from the measured to the measuring, from the measuring to the measured. Thus, considered from the point of view of the measuring, it is impossible by any physical means whatever to reveal a uniform movement of translation in which both the observer and all that he observes participate. Considered from the point of view of the measured, the velocity of light is the only velocity which is unchanged when we pass from one system of reference to another, and in the electromagnetic universe this velocity plays the rôle which infinite velocity formerly played in the mechanistic universe. The constancy of the velocity of light implies further an irreducible plurality of physical measurements of times, because the various groups of observers cannot make clocks from which they can detach themselves and compare them as instruments with one another. They are themselves the inhabitants of a clock, prisoners in their own time-measuring instrument, bound to its state whether they suppose it at rest or moving

To most of us, however, whether our interest in the principle of relativity is scientific or philosophical, the greatest stumbling-block is probably the hypothesis of a finite universe. This seems a contradiction in thought and at least an unnecessary appendage of the principle. Prof. Brunschvicg shows us very clearly why the equations lead necessarily to this hypothesis, for they allow us to show that without it the total reduction of inertia to reciprocal action between masses is impossible.

The metaphysics which the new physics implies means therefore a complete revolution both in philosophy and science. As metaphysics it claims neither priority over science nor independence of it, not even the independence implied by Kant in the theory that the conditions of experience are *a priori*. This is not because metaphysics has learnt to be humble or to be resigned, but because in reality there is a contradiction in the very notion that by reflecting on science we can disengage certain antecedent conditions capable of enclosing all past and future knowledge in static schemes. On the side of positive science we have come to see that by the pure experimental method we are not and cannot be brought into contact with elemental constituents of experience, whether material as Democritus conceived them, or intelligible as Plato conceived them, or sensible as Hume conceived them. The realities we are dealing with in physical science are statistical, so that all reflection on the results of experiment is, not an approach to the absolute, but a progress in the discovery of relativity. The early nineteenth-century ideal of a pure positive science perpetually progressive by means of a division of labour has given place in the twentieth century to a new and more subtle idea, the idea of a progress which is reflective.

(3) Prof. D. Nys's "La Notion d'espace" is a valuable book, but belongs to a different category from that of the two works we have mentioned. It is the fourth volume of his "Cosmologie ou Étude philosophique du monde inorganique," and is encyclopædic in its treatment of the subject. It includes in a general view of the various philosophical doctrines a very clear account of the recent theories with the criticisms upon them and is a model of careful compilation. It develops no original theory and is written from the point of view of neo-scholasticism.

(4) Mr. Shann's short treatise on "The Evolution of Knowledge" is the work of one who knows how to think out a problem for himself. It deals with a different aspect of relativity from that of the physical principle, namely, with the nature of the vital need which has produced in man and some animals the function of knowing. All those friends of Mr. Shann who have received from him from time to time his excellent privately printed pamphlets, bound in the well-known scarlet wrapper, will welcome this published work.

H. WILDON CARR

Ceremonial Exchange.

Argonauts of the Western Pacific: An Account of Native Enterprise and Adventure in the Archipelagoes of Melanesian New Guinea. By Dr. Bronislaw Malinowski. Pp. xxxii + 527. (London: G. Routledge and Sons, Ltd., 1922.) 21*s.* net.

IN this volume Dr. Malinowski has given the first-fruits of his extended stay in the Trobriands, a group of islands off the south-east of New Guinea. A good deal of more or less desultory information, published in Government reports and elsewhere, has indicated that these islanders differ in some respects from their neighbours; Dr. Malinowski now shows how intimately they are all associated with one another, not merely by ordinary trade, but by a hitherto unrecorded and very remarkable system of ceremonial

exchange, known as Kula, with which this book is almost solely concerned.

The exchange takes place between partners who may reside in the same island, but for the most part in different islands. The Kula articles of value are shell-necklaces of a special type and armlets made of Conus shell. The former always travel N.-E.-S.-W., *i.e.* clockwise, and the latter in the contrary direction, but other articles of value may be implicated in the transactions in a subsidiary manner. The islands mainly concerned in Kula are those between Nada and the Trobriands, the Amphletts, part of the southern d'Entrecasteaux and the Tubetube group. The real Kula necklaces and the arm-shells have various worth, and highly valued ones have individual names, and their wanderings are followed with interest. The ownership, or rather trusteeship, of each object is temporary, and ranges from a few minutes to one year or possibly two, but a man who retains an object beyond a year is regarded as a mean person. The exchange is by the natives sharply differentiated from barter, as no haggling takes place. An equivalent gift is always expected, but cannot be demanded or enforced, the only punishment for failing in this being loss of esteem. If at any time an equivalent gift cannot be bestowed, intermediate gifts will smooth the way till the real repayment takes place. Meanness is the most despised vice, and generosity the essence of goodness. *Noblesse oblige* is in reality the social norm regulating their conduct. This does not mean that people are always satisfied and that there are no squabbles nor even feuds about the transactions. It is obvious that however much a man may want to give a good equivalent for the object received, he may not be able to do so; and then, as there is always a keen competition to be the most generous giver, a man who has received less than he gave will not keep his grievance to himself but will brag about his own generosity and compare it with his partner's meanness; the other resents it, and the quarrel is ready to break out. All the preparatory activities, as well as those connected with the voyages and the ceremonies of exchange, are permeated by magic, as indeed is the whole economic life of the people.

The most important character of Kula is the mental attitude of the natives towards it. The objects of the Kula are neither used nor regarded as currency, as they are never used as a medium of exchange or as a measure of wealth; they serve merely to be owned and displayed and then exchanged. It is through being the means of arousing envy and conferring social distinction and renown that these objects attain their high value and form one of the leading interests in native life. The ceremonial attached to the act of giving and the manner of carrying and handling shows distinctly that they are not mere merchandise, but something that confers dignity on a man, that exalts him, and which he therefore treats with veneration and affection. Nothing of the same kind has been described elsewhere, but something analogous may be discovered now that attention has been directed to it. The potlatch of British Columbia, for example, is worth reconsidering in the light of this book.

Dr Malinowski has not confined himself to a mere detailed description of Kula, but he has endeavoured, apparently with great success, to explain its psychological significance. Kula so pervades the life, thought, and emotion of the people concerned in it that it seems in some respects to fulfil functions which are characteristic of many religions, but with magic supplying the place of spiritual powers. The system might almost be termed the Kula cult, as Dr. Malinowski seems to hint; but he distinctly states that the natives worship nothing.

The inter-insular Kula requires seaworthy canoes, and Dr. Malinowski describes how these are made, and the series of magical rites which accompany every stage in their manufacture, equipment, and sailing. The smaller fishing canoes are owned by one man, but the sea-going canoe is constructed by a group of people; it is owned, used, and enjoyed communally, and this according to definite rules, all of which are described with careful detail and psychological insight. To the natives a canoe of this type is a marvellous achievement, a thing of beauty, and an object permeated by magic. "He has spun a tradition around it, he adorns it with his best carvings, he colours and decorates it. It is associated with journeys by sail, full of threatening dangers, of living hopes and desires to which he gives expression in song and story. In short, in the tradition of the natives, in their customs, in their behaviour, and in their direct statements, there can be found the deep love, the admiration, the specific attachment as to something alive and personal, so characteristic of the sailor's attitude towards his craft."

An outstanding merit of this book is that it is a well considered study in ethnographical method; indeed the author's remarks on field-work will prove of great value for the guidance of future workers. A large number of magical formulæ and oral texts is given in the native language and in translation, which provides unusual documentary evidence of exceptional value for the elucidation of native psychology. The book is well illustrated and of reasonable cost, for which the publishers are to be thanked. Mr. Robert Mond and others, by their liberality, have enabled these investigations to be made, and they have the satisfaction of knowing that they have afforded an

opportunity for a young student to produce a work of absolutely first-class value. It is to be hoped that Dr Malinowski will be able to publish in full the remainder of his material, which, judging from this sample, will mark a distinct progress in ethnographical research and interpretation. A. C. HADDON.

Pure and Applied Electricity.

(1) *Einführung in die Theorie der Elektrizität und des Magnetismus. Zum Gebrauch bei Vorträgen, sowie zum Selbstunterricht.* Von Prof. Dr. Max Planck. Pp. v + 208. (Leipzig: S. Hirzel, 1922.) 42 marks.
(2) *Elettrotecnica elementare con numerosi problemi.* By A. Occhialini. Vol. 1: *Magnetismo—Elettrostatica—Elettrochimica—Elettrodinamica—Elettromagnetismo—Induzione elettromagnetica.* Pp. x + 344. (Firenze: Felice Le Monnier, n.d.) n.p.
(3) *Installations électriques industrielles: choix du matériel.* Par R. Cabaud. Pp. 316. (Paris: J.-B. Baillière et Fils, 1922.) 10 francs.

THE first of these three books discusses the groundwork of the theory of electricity, the next discusses the experimental laws and their laboratory applications, and the third is a severely practical work for the commercial electrician. They are all introductions to the subject, but they are intended for very different classes of readers.

(1) Dr Max Planck's work is philosophical, and presupposes a knowledge of mathematics and of the mathematical theory of electricity which is possessed by few. The foundations on which the ordinary mathematical equations rest are examined, and particular stress is laid on the units in which they are measured. The Gaussian, the electrostatic, and the electromagnetic systems of units are considered. The work will be very welcome to the pure theorist and will increase his confidence in the soundness of the physical basis of the mathematical theory. The clear distinction made between magnetic force and magnetic induction is very convincing. The experimenter will find little that is directly helpful to him in this book, but he will appreciate, however, the author's method of getting the capacity of an ellipsoid and the deductions that can be made from it.

(2) The second work under notice is very similar to the standard English books on experimental electricity and magnetism. The author's descriptions of the main phenomena are very clear, and the numerous examples given are instructive. A very full discussion is given of the problem of a number of batteries of different electromotive forces and resistances in parallel with one another. A thorough knowledge of this problem is a great help to students when they come to the corresponding problems of dynamos or alternators running in parallel with one another. The definition given of the temperature coefficient of metals, however, is not sufficiently accurate for modern requirements. The rating of a dynamo depends on its temperature after a run at full load, and the temperature of the coils is computed from their measured resistance and a knowledge of the temperature coefficient of copper. As the problem is one of great commercial importance it is necessary to distinguish between the temperature coefficient of the volume resistivity, the mass resistivity, and the constant mass resistance. These are all different and vary with the lower of the two temperatures considered. The approximate formulæ for the self-induction of a coil are given, but we think that their limitations should have been stated.

(3) M. Cabaud's book is very general and can be appreciated only by a technical expert. It presupposes a thorough knowledge of practical electrical engineering. In the first section of the book a general discussion is given of the kind of electric machine required to do special work, for example, whether a direct-current or an alternating-current machine will be the more useful. In the latter case also the question of whether it is to be single phase or polyphase is considered. The efficiency of the machine, its heating under load, the electric strength of the insulating wrappings, etc., have all to be considered. In the second section the characteristics of the machines, whether rotating or stationary, are described. In the last section the usefulness of the various characteristics are discussed, and the important question of the best guarantees that should be demanded from the manufacturers is considered.

The Petroleum Industry.

(1) *Encyclopédie Scientifique: Bibliothèque de géologie et de minéralogie appliquées. Les Gisements de pétrole.* Par Jean Chautard. Pp. viii + viii + 330. (Paris: Gaston Doin, 1922.) 14 fr.
(2) *The Oil Encyclopedia.* By Marcel Mitzakis. Pp. xvi + 551. (London: Chapman and Hall, Ltd., 1922.) 21*s*. net.
(3) *The Economics of Petroleum.* By Joseph E. Pogue. Pp. ix + 375. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 33*s*. net.

THE "Encyclopédie Scientifique" constitutes a comparatively new departure in French technical literature, and has for its scope the ultimate publication of some thousand volumes dealing with the various phases of pure and applied science. M. Jean Chautard's

little book (1) is apparently one of the earliest of the series, and if it indeed sets the standard of future productions, this encyclopedia will undoubtedly prove of very great value. Well written, profusely illustrated with photographs, maps, plans, diagrams and sections, this particular volume covers a wide subject in a minimum of space. The major part is concerned with the geology of petroleum and a consideration of the petroliferous regions of the world Other chapters deal with the nature of petroleum, natural gas and solid hydrocarbons, their origin, mode of occurrence, surface manifestations, exploration, and economic development

The author has drawn on most of the more recent literature for his descriptions of the oil occurrences throughout the world, and in consequence the information given is most up-to-date; several minor errors occur in the spelling of place-names, but these will doubtless be corrected in a future edition. Not the least valuable of the contents of the book are the bibliography, and a noteworthy preface by M Louis Mrazec, whose structural theories, incidentally, receive careful treatment in the text At the present time, when scientific books are usually published at prohibitive prices, it is gratifying to be able to recommend a volume which is both an inexpensive and necessary addition to the library of petroleum technology

(2) In the "Oil Encyclopedia," by Mr Marcel Mitzakis, we meet with a very different type of book, one which will doubtless make its appeal more to the commercial than to the scientific community To the many people whose province it is to control the destinies of oil-land development and economies -the administrative as distinct from the technical branch of the industry this volume will prove of value, presenting as it does the many and varied phases of oil-mining in the form of an elaborate and explanatory index. The volume includes information of a biographical, geological, geographical, and chemical nature, apart from its treatment of the multitudinous technical factors pertaining to the oil industry, and as a source of broad reference to such matters, has much to commend it. It lacks in many cases, however, that atmosphere of authority and degree of accuracy which are to be expected in a work purporting to be for widespread use, and judged from the scientific point of view, leaves much to be desired. In several cases the definitions, especially of geological terms, are decidedly loose, if not actually erroneous, while some of the facts given are by no means correct, nor are they always up-to-date. As examples we may quote the definition of "æolian" given as "a special kind of sand found in oil-bearing strata," and the paragraph devoted to the explanation of the word "Cambrian" since "so many oil strata occur disseminated among Cambrian deposits." Further, the oil potentialities and realities of Great Britain are allotted space out of all proportion to their importance, while the remarks on the natural gas resources of Heathfield, Sussex, though optimistic, are unfortunately incorrect

No work of this nature could possibly be complete, in the strict sense of the word unless expanded into many volumes, and had the scope been a little less ambitious, the result would probably have proved far more satisfactory The biographies could well have been dispensed with, similarly many of the definitions of the more complex chemical compounds, and thus space made available for the inclusion of many terms used in drilling, for example which are unintelligible to the average non-technical man

(3) The object of Mr Joseph Pogue's book is to present, in perspective, the more important economic facts relating to petroleum, and it must be said that the author has certainly achieved his aim He had every opportunity of producing an enormous compilation of statistics, relieved by a few terse, explanatory paragraphs and deductions, a veritable "blue-book" in fact, dreary, lifeless, and incomprehensible, as publications of that nature are usually wont to be Instead, the author has given us a work of tangible value, one which seeks only to use past and present facts in order to foreshadow future possibilities

People to-day are very apt to take things in general, and the petroleum industry in particular, for granted, and ignoring such factors as gradual and universal decline of oil production, more especially in the United States, they are blind to the economic situation which must inevitably be faced Not only that, they are content to consume oil-fuel and allied products on a peculiarly wasteful scale at the present time, in a manner as complacent as it is incomprehensible to the careful thinker We recognise in this the basis of Mr Pogue's book He says, "The point to be emphasized is the coming necessity for increasing the over all efficiency of petroleum . . .", and having read that and other important observations made in his excellent preface, we are not surprised at the skilful manner in which he handles his ramified subject. The volume is very readable indeed, it demands most careful perusal as it takes the reader rapidly from one aspect to another. Beginning with the economic organisation of the industry, it sets before us the salient features of the present trend of oil-field development, oil refinery practice, oil marketing, finance and the bearing of automotive transport on the industry, among other factors, while the chapters on resource situation, international aspects of petroleum, the full utilisation of petroleum, and the

function of statistics in the industry, are especially good.

In the space at our disposal, it is impossible to review a work of this nature with justice, and likewise to indulge in that amount of constructive criticism otherwise desired; we would suggest that, in view of its importance as an ultimate source of fuel, considerably more space be devoted to the oil shale question in future editions, while present refinery practice might with advantage be much more severely criticised, both with regard to technique and design. The author is to be congratulated on the achievement of a remarkably fine work, one that should be widely read by all serious servants of a great industry. H. B. MILNER.

Our Bookshelf.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol. 20. *Lead and Zinc. The Mining District of North Cardiganshire and West Montgomeryshire.* By Dr. O. T. Jones. Pp. vi + 207. (London: H.M. Stationery Office, 1922.) 7s. net.

LIKE the three previous volumes dealing with British lead and zinc ores which have been issued by the Geological Survey, it must be admitted regretfully that the present one has a scientific rather than an economic interest. Some of the mines described in the present volume, like Frongoch mine in Cardiganshire and the Van mine in Montgomeryshire, have been extraordinarily productive; the former has been worked for 59 years and the latter for 51 years, and from each more than 100,000 tons of lead and zinc ores have been produced in the course of its career, but in both cases the really productive period was something like half a century ago. The author suggests that it is just possible that these mines might show an improvement by sinking deeper and reaching harder rocks than the soft shales in which they are now bottomed; the prospect, however, is not a very promising one, and the present low price of lead affords no encouragement to spend money on prospecting operations of a highly speculative nature.

The real value of the present work lies in the excellent study of the formation of the faults and fissures and the mode of their filling which Prof. Jones has supplied in the introductory chapters. The first chapter on the general structure of the area gives a very valuable summary of its leading geological features, while the next two chapters are devoted to a discussion of the leading system of fissures to which the district owes its mineral wealth. Finally, the last chapter deals with a number of important points such as the probable age and sources of origin of the ore filling, and the influence upon it of the country rock traversed by the fissures. These chapters form a most valuable contribution to the study of mineral deposition, and from this point of view, quite apart from any possible remote economic possibilities, Prof. Jones's volume deserves the careful attention of the student of mineral deposits. H. L.

Some Scottish Breeding Duck: Their Arrival and Dispersal. By Evelyn V. Baxter and Leonora J. Rintoul. Pp. vii + 90. (Edinburgh: Oliver and Boyd, 1922.) 5s. net.

THE problems of the increase and extension of range of ducks in Scotland, and in other countries, have long exercised ornithologists throughout the British Isles. As the authors of the volume under notice point out, protection and a better feeling towards and a greater interest in all wild birds are probably important factors in the case but do not explain everything. Certain species other than ducks are as steadily decreasing, and the rise and fall of a species is a complicated biological problem which may have but indirect association with human interference, or may be due entirely to other causes. The recent colonisation of Scotland by other birds, such as the starling, turtle-dove, and great-crested grebe, may be due to the necessity for an over-abundant species to find new areas and the possibilities of settling in an area where raptorial birds and other enemies have been largely destroyed by man's advance and action.

One factor the authors have not stressed, the growing habit of keeping pinioned ornamental fowl, though they mention bird sanctuaries. Passing birds are often "called down" by pinioned fowl, and some of them may elect to mate and breed. That the direction of spread differs in such ducks as the gadwall and wigeon is no argument against this fact, for the source whence come the visitors has no bearing on the influences which cause them to remain. Many pairs of ducks of various kinds have probably nested in out-of-the way places for years and been overlooked, for it is only within the last thirty years or so that parts of Scotland have been systematically explored from the ornithological point of view. Sportsmen and keepers are not very particular about the species of the ducks which fill their bags.

We note that the authors use the correct spelling of two much-discussed names, wigeon and shoveler.

An Introduction to Engineering Drawing. By J. Duncan. (Life and Work Series.) Pp. x + 158. (London: Macmillan and Co., Ltd., 1922.) 4s.

THE aim of Mr. Duncan's book is to enable young students of engineering to produce intelligible working drawings of the details of engineering machines and structures. The student is introduced to the proper workmanlike methods of actual engineering practice, and is not allowed the use of any special hybrid methods which are supposed by many to be sufficient for use in schools.

The book commences with a description of drawing instruments, their use and handling; from this, the student is led to the ordinary problems in plain geometry with practical engineering examples such as drawing cams, and plotting small surveys. Afterwards, a little solid geometry introduces the student to oblique and isometric projection, and prepares him for the drawing of engineering details. For this latter portion of the training the author strongly recommends the use of models. A commencement is made with simple fastenings such as bolts and nuts, then the more complicated connexions are dealt with, as exemplified

in tie bar joints, cotter joints, and coupling boxes. The following chapters deal in succession with other engineering details, such as belt and rope pulleys, chain drives including sprocket wheels, bearings of various kinds, and details of shafting, cylinders, and pistons. Finally, structural details involving the usual angles, tees, and channels with the more elaborate columns, girders, and roof truss joints in which the sections are employed give the student a useful introduction to this side of engineering practice.

The book covers much ground in its 158 pages. It is very clearly written, and the publishers' part, in so far as concerns the type and diagrams, is quite perfect. For the purpose of familiarising the budding engineer with the elements of machines and structures the author has produced a most excellent book.

Juvenile Delinquency. By Henry Herbert Goddard. Pp. vi+120. (London: Kegan Paul and Co., Ltd., n.d.) 3s. 6d. net.

No student of modern life can fail to be perturbed by the number of juveniles who come before the courts yearly for offences covering a very wide range. That our present system does not deal with them adequately is obvious.

Delinquent behaviour is fundamentally unsocial behaviour, *i.e.* the child is obeying his own instincts instead of modifying them according to the demands of society. It becomes therefore necessary to ask why a child behaves unsocially. These unsocially behaved children fall into at least two groups, (*a*) those who are mentally too unintelligent to understand social behaviour, and (*b*) those known as psychopaths, who, while having normal intelligence, have not normal control.

The author suggests that these children should be cared for by some bureau organised by the State, which should undertake research work, be able to diagnose cases before the behaviour has become seriously wrong, and also to control the lives of those who will never be able to control them for themselves. He describes in this connexion the Ohio Bureau of Juvenile Research which, although only established in 1914, has yet justified itself by its work.

Outwitting our Nerves: A Primer of Psychotherapy. By Dr. Josephine A. Jackson and Helen M. Salisbury. Pp. viii+403. (London: Kegan Paul and Co., Ltd., n.d.) 7s. 6d. net.

The stream of books concerned with explanations of modern psychologists in general, and of Freud in particular, for people of little or no psychological knowledge, still flows on. Many fail entirely in their avowed object, being either too condensed to be intelligible, or too popular to be scientific. The effect of a conversion to Freudian doctrines is, only too frequently, of the nature of a wholly uncritical acceptance of much that Freud would call problematical. It is therefore a relief to turn to this book, which not only gives a very fair and balanced account of the findings of psycho-analysis, but also keeps these findings in perspective, showing them in relation to the known laws of biology and psychology. The whole book is characterised by a sense of humour foreign to many writers on the subject, and by sanity of outlook. Written in an easy and popular style it can be safely recommended to the student of, or sufferer from, "nerves," and even to the reader already cognisant with the literature of psycho-analysis it will prove helpful and interesting.

Imperial Institute: Monographs on Mineral Resources with Special Reference to the British Empire. Silver Ores. By Dr. H. B. Cronshaw. Pp. ix+152. (London: John Murray, 1921.) 6s. net.

This addition to the useful Imperial Institute Monographs gives details and statistics of the sources of silver throughout the world. In 1918 the British Empire produced nearly one-fifth of the world's supply, Canada being responsible for the larger part of this amount. The United States headed the list of producers during the war period, but has now been passed again by Mexico. About two-thirds of the world's silver comes from base metal ores, and much of the remainder is obtained from ores worked primarily for gold, so that silver is mainly a by-product of other metallurgical operations. The extraction and uses of silver are dealt with only very briefly in this monograph, and some information as to the metallurgical processes employed in the most important mining regions would have added to its value. This remark applies particularly to the account of the rich and metallurgically interesting Cobalt district of Ontario, which is responsible for the greater part of the Canadian production. These monographs provide much information in a handy form.

A Systematic Qualitative Chemical Analysis: A Theoretical and Practical Study of Analytical Reactions of the more Common Ions of Inorganic Substances. By Prof. G. W. Sears. Pp. xi+119. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 8s. 6d. net.

The introductory part of the work under notice contains a brief account of such matters as equilibrium, ionisation, and solubility product. The section on the detection and separation of the metals is in the form of numbered experiments, and is much less clear and useful than the usual arrangement in tables. The explanations of the reactions, however, are very clearly and fully described, and would be useful in supplementing analysis tables. The section on acids relies on precipitation methods with a single sample, and all preliminary tests are omitted. This seems to be a mistake, as many acids are readily found by simple preliminary methods. There appear to be no features which would indicate any marked superiority of the book over existing treatises.

An Introduction to the Chemistry of Radio-Active Substances. By Dr. A. S. Russell. Pp. xi+173. (London: J. Murray, 1922.) 6s. net.

There is at present a real need for a small but up-to-date book on radioactivity, in which the subject is dealt with from the chemical as well as the physical side. Dr. Russell's book would seem to supply this need very satisfactorily. It is not overburdened with detail, but gives a balanced account of the subject, which will be found very useful to students. A particularly good feature is the inclusion of the chemical methods of separation and analysis, which sometimes tend to get lost in theoretical speculations.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dampier's "Discourse of the Winds" and the Distribution of Wind on the Earth's Surface.

DAMPIER'S "Voyages" are well known, at any rate by name, but his "Discourse of the Winds" is seldom referred to. It is, however, well worth careful examination and, so far as I can judge, contains as much information about the distribution of winds as any of the modern works on the same subject.

In this "Discourse" Dampier propounds no theories, but aims at setting down the general character of the winds encountered by ships in all parts of the world, using for this purpose his own observations, and such other information as he has gathered from sources which he considers trustworthy.

It must be remembered that in Dampier's time (late seventeenth and early eighteenth centuries), the ships employed even for the longest voyages were small, and the direction and strength of the prevailing winds were much more important to navigators than they are at the present time. It is true that there are still plenty of small sailing craft in various parts of the world, the captains of which are probably well acquainted with local conditions, but these men as a rule are not of the type who place their knowledg on record. With the "Discourse" Dampier publishe maps of the hemispheres in which his observations ar summarised.

For his purposes he divides the earth's surface int four regions, namely, the two trade wind areas anc those to the north and south of them. These latter h calls the "Regions of Variable Winds." The direc tions of the trades are indicated in the maps by line and arrows, but naturally and rightly the regions o variable winds are left blank.

No indication is given of the directions of the winc on land, but what he calls coastal winds, that is wind the direction of which is influenced by the proximity of land, are shown in some detail.

Parts of the maps are here reproduced (on the original scale) which show that "coastal" influence in the trade wind areas extends farther to the west (*i.e.* to leeward) of the continents than to the east.

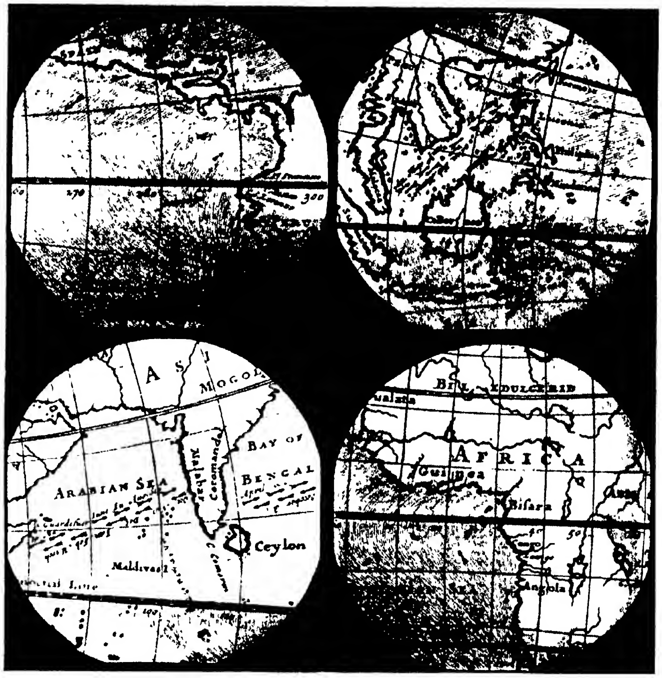

FIG. 1.—Reproduction of parts of Dampier's Maps to show coastal winds in the trade wind areas.

Although it is impossible to determine *a priori* what the true wind should be at any given spot, it is not without interest to consider what would happen in certain imaginable conditions much simpler than those actually existing, and to see whether in such conditions the air currents, etc., would at all resemble those which are observed.

Starting with the earth as the only body in the universe, without rotation, and at a temperature of absolute zero, let its surface be uniform and level, and let its volume and that of adjacent space be divided into elementary conical cells proceeding from the earth's centre. Let the walls of the cells be non-conductors of heat but transparent to radiation.

Now let this earth be warmed by a source of heat equivalent to the sun, but in the form of a distant ring surrounding it in the plane of the equator. Let the atmosphere be transparent to radiation and take its heat only from the floor of the cell which contains it.

In the course of time the contents of each cell will reach the temperature of the floor, which will be a maximum at the equator, and will vary as the cosine of the latitude to absolute zero at the poles.

The barometric pressure in each cell will be the same; were all the cells removed the atmosphere would be in equilibrium. The equilibrium, however, would be unstable, and the least departure from the original stratification of density would cause ultimately a circulation to be set up, in which, in the absence of turbulence, warm air would flow from the equator towards the poles at high levels, while cooled air would travel in the opposite direction near the surface of the earth. A steady distribution of temperature would be reached when each element of the surface lost by radiation as much heat as it received from the source plus that supplied by the circulation, and this distribution probably would not differ much from that which now exists, though the fact that the real atmosphere is more or less opaque to long waves would introduce a sort of "green-house" effect, and raise the mean temperature above that appropriate to perfect transparency. Again if the imaginary earth were completely covered by a deep ocean, a separate circulation would be set up in the latter, and the temperature distribution would be somewhat modified in the direction of greater uniformity.

Since the energy of the circulation is derived from the source of heat, there will be no change of pressure due to the velocity, and supposing for the moment that the air is incompressible, then in the nearly horizontal path which constitutes the greater part of each stream line circuit, the cross-section velocity and dynamic head for each will be constant, though not necessarily the same for different streams. The cross section of the ascending and descending parts of the streams will bear to the cross section of the horizontal part the ratio of the length of the earth's quadrant to the height of the homogeneous atmosphere, and thus in the neighbourhood of the poles and the equator there will be a small increase of pressure. The form of the stream lines due to temperature circulation in a spherical shell is indicated diagrammatically in Fig. 2.

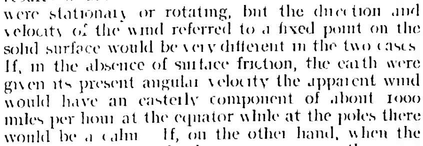

Fig. 2.—Stream lines of the circulation in a meridional element of a spherical shell, the density of the fluid being supposed constant.

As regards the distribution of temperature, the results would be much the same whether the earth were stationary or rotating, but the direction and velocity of the wind referred to a fixed point on the solid surface would be very different in the two cases. If, in the absence of surface friction, the earth were given its present angular velocity the apparent wind would have an easterly component of about 1000 miles per hour at the equator while at the poles there would be a calm. If, on the other hand, when the rotation was started, the air was given the same velocity as the surface under it, the apparent wind would vary in direction and force in a period equal to that of the circulation.

In the real atmosphere, the effects of turbulence, viscosity, and surface friction will ensure that the average velocity of the apparent wind shall in no place exceed 30 or 40 miles per hour. If unresisted air passes from lat. λ to $\lambda + \Delta\lambda$ the change of the linear speed of the ground under it, *i.e.* the change in the E. or W. component of the apparent wind, is $R\Delta\lambda(1 - \sin\lambda)$ linear velocity in longitude, and if the apparent wind remains constant, it shows that surface friction is sufficient to accelerate or retard the atmosphere by this amount in the time taken in covering the distance $R\Delta\lambda$. In the case of the earth, this would imply that if the circulating velocity (*i.e.* the N. or S. component) is 15 m.p.h., surface friction suffices to change the speed of the apparent wind by about 15 m.p.h. per hour near the poles while in lat. 30° the corresponding change would be somewhat less than 2 m.p.h. per hour.

On the imaginary seasonless earth, the average wind would everywhere be a definite function of the latitude and coefficient of friction, provided that the going and returning parts of the circulation did not mix on the journey, and in low latitudes this would be true even when the effects of turbulence were taken into account. Farther north or south, however, the hot and cold streams would become interwoven in eddies the forms of which are incalculable, though the average winds would always be either from N. and E. or S. and W. Thus it might be expected that there

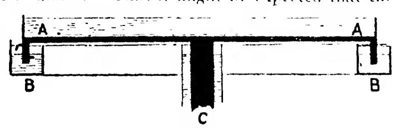

Fig. 3.—AA, Circular conducting plate and tank. BB, Annular hot water trough. C, Axis and cold water tank.

would be calms at the equator, moderate and regular trade winds for some distance on either side, and beyond these, irregular winds, the intensity of which increased with the latitude. The barometric pressure would be nearly constant except in the eddies, and there the variation of pressure would depend, not on the actual velocity of the apparent wind, but on its difference from the average for the latitude.

Such a description with modification depending on the seasons, the presence of moisture in the air, and on the distribution of land and water agrees with the average conditions on the real earth. Dampier's maps show that coastal influence may be sensible through 10° of longitude or more, and it may be guessed that the direction of the monsoons is in some way influenced by the great area of land lying to the north of the parts where they blow.

There is not much information available concerning the wind structure of the atmosphere on the borders of the Trades, and a proper investigation of this subject would form an important addition to meteorological science; but such an investigation would require more than one *Challenger* expedition devoted to the exploration of the upper air instead of the deep sea.

Expeditions of this kind are not likely to be undertaken at the present time, but some notion of the manner in which the Trades break up might be gained by an experiment such as is indicated in Fig. 3, where a thick circular metal plate, provided with descending flanges at the circumference and a thick central axis, carries a shallow circular tank containing fluid. The flanges dip into a circular trough of warm water while the axis is kept cold. If the apparatus is stationary, a circulation is set up in the tank of the type shown in Fig. 2, but if it has an appropriate angular speed about the axis, the

conditions will have a certain similarity to those existing in the atmosphere. The difference in the character of the circulation in the two cases could scarcely fail to give some useful hints

Another illustration of the kind of flow to be expected near the borders of the Trades may be observed (although the analogy is not so close as in the experiment) whenever a current of water flows into a pond The central part of the stream continues on its course for some distance unbroken, but the margins are bordered by eddies, which (looking down stream) are right-handed on the right, and left-handed on the left side, and consist of equal volumes of water from the stream and from the pond wrapped together after the fashion of a "roly-poly" pudding When once formed, they have a certain life of their own, and follow erratic courses, often generating secondary eddies further from the main stream In general their life is short, but occasionally vertical components in the flow of the main stream give rise to components in the eddies parallel to their axes, and in such cases the vortices may be sustained and intensified

Much the same sort of action must be going on at the borders of atmospheric currents, and it must happen, especially in the turbulent regions, that either on account of the general circulation or from local causes, warm air will sometimes underlie colder strata, and this is what is required to prolong the life of eddies or vortices with vertical axes

It may be said with some confidence that tornadoes, sand pillars, and waterspouts are due to local causes of this kind, and it seems highly probable that the deep barometric depressions which accompany the greater storms have a similar origin depending on inversions of level of the general circulation In referring to warm and cold strata, the temperature must be supposed to be compared at the same altitude since, so far as thermometric readings are concerned, the upper air is always colder than that near the ground A MALLOCK

The Conditions of Sex-change in the Oyster (*Ostrea edulis*).

IN the issue of NATURE for August 12, p 212, and in several previous numbers, Dr Orton has given some interesting information concerning the old question of the breeding habits of oysters, especially sex-change and its conditions This problem has been discussed in a certain number of ancient treatises (Davaine, Van Beneden, Lacaze-Duthiers, Hoek, etc), but has been but little investigated in the course of the last few years During my work at the Danish Biological Station I have, since 1919, been making experiments and investigations on the biology of the oyster in the Limfjord As my results in several respects confirm and amplify those of Dr Orton, I will give here a short account of some of the most important In the course of the winter a more detailed paper will probably be published in the Report of the Danish Biological Station

Dr Orton confirms the observation, made by Mobius, that in European oysters a specimen directly after breeding produces spermatozoa, and I fully agree with him In several cases I have proved, through experiments with oysters, in the shells of which a little hole had been bored, that an oyster in the course of less than a week changes from a female to a male

Dr. Orton further mentions the interesting fact that he has been able to state that an oyster born in 1921 was spawning already in 1922, thus phenomenon he ascribes, and very rightly, to the high temperature of the summer 1921. I have investigated several thousand oysters in the Limfjord, the youngest female found by me was at least three years old which is no doubt due to the lower temperature of the Limfjord Neither did I ever find that oysters had ripe spermatozoa in the summer in which they were born, in the Limfjord that phenomenon only occurs in the following summer Formerly the earliest time for an oyster to breed was much discussed If we examine from where the different authors have obtained their material, it appears that those who advocated early breeding had got theirs from Southern France, while those who advocated two to three years as the age for breeding had had material from the English Channel and the North Sea

From my experiments, and from the study of previous papers on this subject, I have come to the conclusion that the duration of the male stage depends on temperature, so that the colder it is the longer the stage lasts At the temperature which ordinarily prevails in the Limfjord (15°-16° in July), this stage will last three to four years The oyster, therefore, breeds for the first time (the first stage being the male stage) when it is three to four years old, further, every single oyster individual in ordinary circumstances of temperature breeds only every third or fourth year, in especially cold years still less often, in warm years more often These phenomena, together with the shorter duration of the female stage, explain the fact that in a certain number of oysters in the Limfjord we always find only a relatively small percentage of females This likewise explains why the oyster breeds more sparingly the further north it is, and decreases regularly in number without any sharp boundary-line

The breeding of the oyster is in at least three respects influenced by temperature A high temperature increases the number of times an oyster may breed in its life, it shortens the time which the breed passes in the mantlecave of the mother animal, and, according to Hagmeier, it shortens the pelagic larva stage R. Rise in Temperature of Living Plant Tissue when infected by Parasitic Fungus.

WHILE engaged on some work connected with the export of citrus fruits from South Africa to England, we have come across a point of interest to plant pathologists and bacteriologists which would seem worth recording at this stage

In investigating the effects of inoculating oranges and grapefruit with *Penicillium digitatum* we found that a very definite rise of temperature took place in the infected tissue We are not aware of such an observation having been made before in connexion with the invasion of plant tissue by a parasitic fungus, and it will be interesting to ascertain whether a similar rise of temperature takes place in all cases where living plant tissue is attacked by parasitic fungi or bacteria

To what extent direct reaction of the host is responsible for the rise of temperature is still to be determined, certainly no rise of temperature was observed when the host tissue was killed prior to inoculation Mercury-in-glass thermometers were used in making these observations, but the employment of thermo-electric apparatus will naturally be necessary to carry the investigations further

This observation of ours would seem to open up

an entirely new field for research by botanists, and it is probable that it may have an important bearing on the problem of fruit and vegetable transport and storage.

An account of the experiments undertaken to illustrate the above will be published in due course.

Coral in Medicine.

In the serious contributions published in recent issues of Nature on the subject of black coral, no one seems to have remembered that in the "Médecin malgré lui" Molière makes Sganarelle offer a medicinal cheese to Perrin for his mother, thus:

P. Du fromage, monsieur?

S. Oui, c'est un fromage préparé, où il entre de l'or, du corail et des perles, et quantité d'autres choses précieuses.

And Sganarelle's last words are, "Si elle meurt, ne manquez pas de la faire enterrer du mieux que vous pourrez." F. Jeffrey Bell.

Biography of Sir Norman Lockyer.

Miss Lockyer and I are preparing a biography of my husband, Sir Norman Lockyer, in a form which I hope will make it not only of interest to his many friends and admirers, but also a contribution to the scientific literature of the present day. If any readers of Nature happen to possess letters from my husband, I should be greatly obliged if they would give me the opportunity of seeing them. My object in making this request is that any matters of general interest which thereby come to light might be incorporated in the work.

The letters would not be quoted, except with the permission of their owners, and would be returned as soon as their contents had been noted.

T. Mary Lockyer.

Harpoons under Peat at Holderness, Yorks.

At the recent meeting of the British Association at Hull there was a very lively discussion at Section H about some harpoons said to have been found under peat in Holderness. May I ask you to be so good as to spare a little space, in order that I may say more fully what time prevented me from saying then?

There is a doubt about the authenticity of those harpoons. Mr. T. Sheppard believes them to have been *made* by the supposed finder; Mr. A. L. Armstrong, who introduced them to the meeting, believes them to be genuine. I also believe one of them to be genuine, the smaller of the two; about the other I am not so sure. But I expressed no opinion as to whether, if genuine, they were found locally or not, since I have no means of forming an opinion. It is possible that they—or the smaller of the two—were found in archæological excavations abroad, and a fictitious site in Yorkshire given to them later to enhance their interest.

Mr. Sheppard quite rightly says that the discovery of a flint axe of a certain type "in the neighbourhood" proves nothing. But I understood that it was found under a depth of peat. In type it is Campignian, exactly what one would expect to find associated with harpoons of early neolithic type.

There can be little doubt that in Holderness exist remains of the early neolithic age, remains which are older than the Long Barrows. Apart from surface-finds, the pile-dwellings or platforms at Ulrome are evidence of the existence of habitations there which seem to be neolithic; they contained stag's-horn axes of a well-known early neolithic type—though it is true that type survived right through the neolithic period on the continent. There is thus no *a priori* reason for rejecting the harpoons; they are just what I have always expected would be found in Holderness.

However, we cannot use suspect material as evidence, and the best thing to do is to go into the field and test it. If Mr. Armstrong will find a site where flint flakes and implements are to be found under the peat in sufficient numbers to justify digging, I will come and bring a spade with me.

A Curious Luminous Phenomenon.

I hesitate to trespass on your space in describing an observation which may be more common than I suppose.

While standing about twenty yards from the sea-shore and looking due south out to sea, the horizon and a region slightly above it (elevation only about 1° or 2°) were lit up by a faint white light which extended laterally over a segment subtending an angle of about 30°.

The conditions under which this light was seen were as follows: Time, 7.15 p.m.; wind strong from the west, bringing up a good deal of low cloud and very fine rain in the air causing bad visibility; sea rather rough with four lines of breakers at the shore. The appearances of the light were not the same to my wife as to myself. Her impression of it was that it was a light which she saw only if her eyes followed it, yet it consisted of a long streak of light parallel to the horizon with a break in it and then another small streak. My impression was that of a light which appeared to flash up over the horizon, subtending the angles already noted, the flashes not succeeding each other regularly. I had the feeling that my eyes had to be just right for getting the impression at all.

As to the cause, I think we can eliminate that of distant lightning; the weather had not been for many days of a thundery type, and it is unlikely that distant flashes would light up a streak of the distant sky embracing such a wide lateral angle and yet be restricted to an elevation of not more than 2°.

The sky above the horizon was darkly and uniformly clouded at the time, so that the horizon was barely visible, but white-capped waves could be seen far out at sea. The brightest objects in the field of view were the lines of breakers at the shore, and it may be that the retinal images of these being very near to that of the horizon were the cause of the phenomenon. Perhaps some readers of Nature are familiar with this sort of observation and will point to the obvious cause. S. R.

A Fifty-foot Interferometer Telescope.[1]

By Dr. GEORGE E. HALE, For.Mem.R.S.

THE angular diameter of a star was measured for the first time by Mr. Francis G. Pease at the Mount Wilson Observatory on December 13, 1920, with a 20-foot Michelson interferometer attached to the 100-inch reflecting telescope. The method employed is due to Prof. Michelson, who had adjusted the interferometer and tested it on stars during the previous summer, with the assistance of Mr. Pease. Since that time Mr Pease has measured the diameters of Betelgeuse, Arcturus, Aldebaran, and Antares On the basis of the best available values of their parallaxes, the corresponding linear diameters are 215,000 000, 21,000,000, 270,000 000, and 400,000,000 miles respectively. These stars are all in the giant stage, with densities ranging from 0·000001 (Antares) to 0·0002 (Arcturus) The Sun, a dwarf star 866,000 miles in diameter, in a much more advanced state of development, has a density of 1·4 (water = 1).

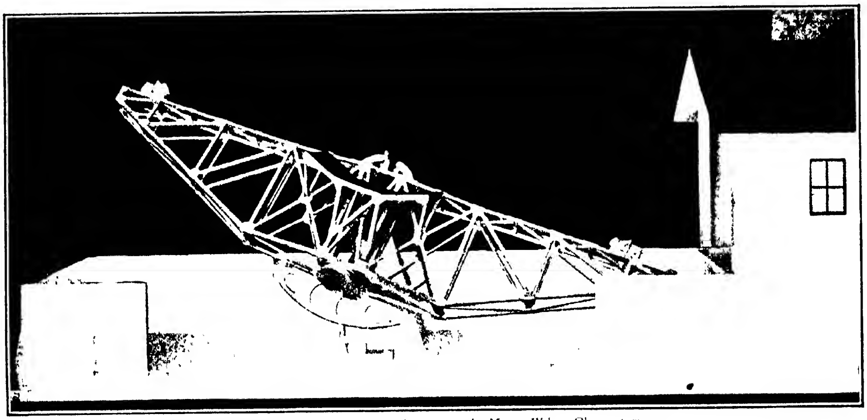

FIG. 1 50-foot interferometer telescope for the Mount Wilson Observatory
Model seen from the north (part of wall removed to show 36-inch mirror cell and driving mechanism)

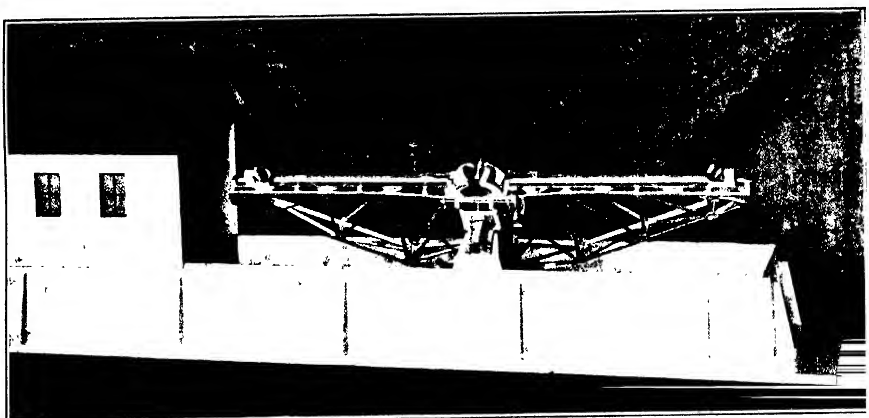

FIG. 2 —50 foot interferometer telescope for the Mount Wilson Observatory
Model seen from the south, showing movable house that covers the instrument when not in use

It would evidently be of great interest to measu[re] the diameters of other stars, of various spectral typ[es] because of the direct bearing of the results on t[he] problem of stellar evolution Unfortunately, very fe[w] are within the range of the 20-foot interferometer, a[nd] neither the capacity of the telescope mounting nor t[he] width of the observing aperture in the dome will perm[it] a larger instrument to be used with the 100-inch r[eflector]

[1] The substance of this article was communicated to Section A of the British Association at Hull on Monday, Sept 11, by Prof H H Turner, who showed the photographs of the model on the screen

flector. Immediately after the first successful measures by Mr. Pease, both he and I made several designs of large interferometers with independent equatorial mountings, but their cost would have been too great to warrant their construction. It was also thought advisable to postpone further instrumental developments until they could be undertaken in the light of prolonged experience with the 20-foot interferometer.[1]

The method has since proved so successful, and its wider application so desirable, that the mechanical problem has recently been taken up anew. Optically the 20-foot instrument leaves nothing to be desired. The new instrument is therefore simply a larger Michelson stellar interferometer adapted for the observation of fainter and smaller stars, embodying no new optical features, but carried by a mounting so simplified in design as to reduce the cost of construction to a minimum. My specifications for the mounting, which have been improved in certain respects and developed into working drawings by Mr. Pease and his associates in the Division of Instrument Design of the Mount Wilson Observatory, call for a light but very rigid skeleton girder about 54 feet long and 10 feet deep at its centre, where its cross-section is about 4½ feet (Figs. 1 and 2). This is to be built of standard steel shapes, cut to length at the mill and riveted together on Mount Wilson. The girder will be bolted to a heavy plate carried by the upper extremity of the polar axis, which is a short steel forging turning in standard roller bearings, mounted on the upper face of a massive concrete pier. The polar axis passes through the centre of gravity of the girder, thus assuring its balance in all positions. A worm-gear sector of long radius, bolted to the girder, is driven by a worm connected with a driving-clock fixed near the north face of the pier. The range of motion in right ascension is 1½ hours east and west, thus allowing ample time for the observation of a star when near its meridian passage.

The optical parts comprise a paraboloidal mirror of 36 inches aperture and about 15 feet focal length, mounted within the girder, as shown in the illustrations. The two outer plane mirrors, each 15 inches in diameter, mounted at 45° on carriages which slide along rails bolted to the upper face of the girder, receive light from the star and reflect it to two similar 45° plane mirrors, fixed in position above the 36-inch mirror, to which they send the two parallel beams. These are returned as converging beams toward the focus, but are intercepted by a (Newtonian) 45° plane mirror above the centre of the girder, which sends the light to the focal plane, in the direction of the north pole. The observer, seated on a platform carried by the girder, makes the necessary adjustments and determines the visibility of the interference fringes corresponding to various settings of the outer 45° mirrors, which are periodically moved apart by a single long screw driven by an electric motor. The distance between these mirrors, when the fringes disappear completely, gives the angular diameter of the star if the mean wave-length of its light is known.

To reach stars north or south of the equator, the two outer 45° mirrors are rotated simultaneously by synchronous motors about the axis joining their centres. In this way any star from the pole to 30° south declination can be observed when near the meridian.

Throughout the design precautions have been taken to reduce the amount of large and expensive machine work to a minimum. The girder need be only approximately straight, as the rails, carefully planed in 12-foot lengths (the limit of our planer bed), will be optically lined up by adjusting screws. The final compensation for length of path will be effected by a sliding wedge, of the type designed by Prof. Michelson for the 20-foot interferometer. Comparison fringes, adjustable for visibility, will be provided as an aid to the observer. The instrument will be covered when not in use by a sheet steel house with double walls, the upper part of which can be rolled away longitudinally by an electric motor.

This interferometer should permit the measurement of more than thirty stars brighter than the fourth magnitude representing a wide range of spectral types. It is now under construction in the instrument and optical shops of the Mount Wilson Observatory.[2]

[1] For a brief account of the 20-foot interferometer and its method of operation, see the chapter on "Giant Stars" in the writer's recent book "The New Heavens," reviewed in Nature of July 15, p. . Full details are given by Messrs. Michelson, Pease, and Anderson in the *Astrophysical Journal*.

Motorless or Wind Flight.

By Dr. S. Brodetsky.

Recent achievements in motorless flight, variously designated as *gliding, soaring*, and *sailing*, have attracted considerable attention, and much discussion has arisen as to the practical and military value of this new development, as well as to its scientific significance. While many authorities anticipate nothing more than the emergence of a new "sport," and ascribe little importance to motorless flights, others of a more imaginative turn of mind foresee great possibilities in this type of aerial navigation. The motorless flying machine has even been proclaimed as heralding the doom of the engine-driven aeroplane!

It is certainly premature to attempt a forecast of the future of flight in a glider. The art of gliding is, of course, older than that of flight in an engine-driven machine: Lilienthal's experiments with gliders were made more than a generation ago, long before any aeroplane containing a motor rose into the air and executed a real flight. But Lilienthal, Pilcher, Chanute, Orville Wright, and others were not able to stay aloft in a glider more than a few minutes; whereas during the recent competitions in Germany, Martens remained in the air nearly three-quarters of an hour, and Hentzen stayed in the air two hours, and later three hours, performing evolutions of an intricate character. It is therefore clear that the art of gliding has entered upon a new phase, and the scientific problems involved merit careful discussion.

As already indicated, there is considerable diversity in the names given to the flights thus carried out

without the aid of a motor. All the three names mentioned above are really unsuitable. The term gliding is reminiscent of descent in an aeroplane, while the real interest of recent events has been in the fact that pilots were able to stay in the air very long without the help of a motor, and in fact performed climbing feats. The term soaring is less unsuitable, but it suggests climbing as the essential thing, whereas, in reality, horizontal flight in a glider is just as different from aeroplane flight as climbing in a glider. Finally, sailing is quite inappropriate as a description of the flight in question. Perhaps the term *wind-flight* is a really suitable name for flying without a motor, as distinguished from *engine-flight* in an aeroplane.

The wind is indeed the main instrument of motorless flight. Whether birds and other natural flyers do or do not derive energy from the air in some mysterious manner of which we have, as yet, no knowledge is a question that does not arise in the present connexion. The successes achieved have been the outcome of careful study of design and of movements in the air. In construction the gliders used look like aeroplanes without engines, and the determining factors in the flights were the various types of winds that blew while the machines were in the air.

It is clear that in a quiescent atmosphere the net result of any motion through the air in a motorless machine must be a diminution in the total energy, *i.e.* in the sum of the kinetic and potential energies. It follows that in the absence of wind, real flight, namely, flight in which the machine maintains its level for some considerable time, or rises still higher above the ground, is not possible without a source of energy like an engine. It is the presence of wind that puts in the hands of the pilot a source of energy, which can be used to neutralise the loss of energy involved in motion through the atmospheric resisting medium.

Although it should be obvious that the wind must be upwards or unsteady in order to supply this energy, it is necessary to say a few words about the case of a steady horizontal wind, since it has been claimed that "once the airman has left the ground he gets his energy from *the wind*, which may be level and steady." This is not correct, as can be proved quite simply. If we write down the equations of motion of a glider through the air under the action of gravity, we get three types of terms:

(1) Accelerations in terms of the motion of the glider relative to the earth;

(2) Gravity components;

(3) Forces and couples due to air resistance, these being functions of the motion of the glider relative to the air.

It is useful to write the first terms, the accelerations, with reference to the motion of the glider relative to the air. When this is done for a steady wind, the resulting equations are exactly of the same form as if there were no wind at all, since the moving "air axes" move uniformly as seen from the "earth axes." This means that when there is a steady wind, we get the actual motion of the glider as seen from the earth, by adding the velocity of the wind to the motion of the glider in still air; in other words, to an observer travelling with the wind, the motion of the glider would not reveal any effects that can be attributed to the steady wind.

In a horizontal steady wind, therefore, real flight is no more possible without an engine than in absolutely windless air. Any argument that leads to a contrary conclusion must have a fallacy somewhere, if we are to have any confidence in the principles upon which all our mechanics are based. It is true that a steady horizontal wind can be used as an aid in gliding. Thus, by pointing his machine into the wind the pilot can get off the ground with less initial speed than in still air. Further, when the machine is already in the air the pilot can, by pointing it with the wind, increase the horizontal distance travelled before reaching the ground again. But a steady horizontal wind cannot make the machine stay at the same level in the air for any length of time, or climb. For these purposes the wind must be upwards or variable.

If the wind is steady, but has an upward component, it helps in the attainment of real flight, which we can call wind-flight. Thus, if a glider is so constructed that in still air it performs a straight line glide with speed U at gliding angle θ below the horizontal, then a steady wind of speed U, blowing at an angle θ above the horizontal, will keep the glider suspended in the air indefinitely, if it points into the wind. And, more generally, if the steady wind has speed U' at an angle θ' above the horizontal, where $U' \sin \theta' = U \sin \theta$, then the machine will fly horizontally with speed $U \cos \theta - U' \cos \theta'$ relative to the earth, if it is given this speed initially against the wind. If $U' \sin \theta'$ is greater than $U \sin \theta$, so that the vertical component of the wind is greater than the rate of vertical fall of the glider in still air, then the glider will climb with horizontal speed $U \cos \theta - U' \cos \theta'$ and upward vertical speed $U' \sin \theta' - U \sin \theta$.

These results are simple and obvious. Given a steady wind with sufficient upward vertical component, a glider can perform real flights and make evolutions similar to those of ordinary aeroplane flight.

It is not necessary, however, to postulate steady upward wind. If the wind is variable, and this is, of course, usually the case, energy can be derived from the wind, even if it is horizontal, or downwards. This can be seen by a little analysis based on the ordinary equations of motion of the glider. Thus suppose that the wind is in a straight line, but of varying speed. If we write the accelerations in these equations in terms of the motion relative to the air we readily find that the motion of the glider relative to the air is the same as if the air were at rest, and a force per unit mass were given to the glider, in a direction opposite to that of the wind and proportional to the acceleration of the wind. If the wind rises steadily from zero to U' in time t, the motion of the glider is found by taking the air to be at rest and assuming that on each unit mass there acts, in addition to the weight, a force U'/gt in a direction opposite to the wind.

If, then, the machine is pointed into the rising wind and the wind varies quickly enough, flying become possible. If the wind is being retarded, similar propulsive effect is obtained by pointing the machine with the wind. It follows that in a fairly sudden gust which can be taken to consist of a quickly increasing

wind, followed by a quickly decreasing wind, the pilot can take advantage of both phases by pointing the machine into the rising wind, and with the falling wind. Quick manœuvring is, of course, essential, as well as an intimate acquaintance with the movements that are always taking place in the air.

With more complicated variations in the wind, more complex results are obtained. It is now clear, however, that the future of wind-flight is associated with three main lines of study.

(1) The motions that are continually taking place in the atmosphere need to be studied, not only the meteorological wind phenomena as ordinarily understood, but particularly the detailed air motions, the "internal structure of the wind."

(2) Motorless flight presents problems of design that are different from those of ordinary aeroplanes. This is because the glider is a much lighter machine than the aeroplane. Stability is essential, but easy control is a *sine qua non*, since so much depends upon taking as full advantage as possible of any temporary, and often unanticipated, motion in the air.

(3) The rigid dynamics of wind-flight is also an important factor in the progress of the art. Only in very exceptional circumstances can the motion of a glider be steady. Upward steady winds, or uniformly varying winds, are only of rare occurrence and brief duration, and in trying to perform real flight in an engineless machine the pilot must make use of any stray wind that comes to his aid. The motion in wind-flight must consequently be very variable. In this respect wind-flight must generally differ in essence from engine-flight. In the latter steady flight is the rule, in the former steady flight is bound to be a comparative rarity. The pilot must therefore learn from experience and from calculation to know what to expect from his machine under different conditions. The dynamics of wind-flight should be a fruitful subject of study both for the aviator and the mathematician.

The Influence of the late W. H. R. Rivers on the Development of Psychology in Great Britain.[1]

By CHARLES S. MYERS, C.B.E., M.A., M.D., Sc.D., F.R.S.

A MOURNFUL gloom has been cast over the proceedings of our newly born Section. Since its inauguration twelve months ago this Section, as, indeed, psychology in general, has suffered an irreparable loss through the sudden death, on June 4 last, of him who was to have presided here to-day. When only a few weeks ago, it fell to me, as one of his first pupils, to occupy Rivers's place, I could think of little else than of him to whom I have owed so much in nearly thirty years of intimate friendship and invaluable advice, and I felt that it would be impossible for me then to prepare a presidential address to this Section on any other subject than on his life's work in psychology.

William Halse Rivers Rivers was born on March 12, 1864, at Luton, near Chatham, the eldest son of the Rev. H. F. Rivers, vicar of St. Faith's, Maidstone, and of Elizabeth, his wife, *née* Hunt. Many of his father's family had been officers in the Navy—a fact responsible, doubtless, for Rivers's love of sea voyages. The father of his paternal grandfather, Lieutenant W. T. Rivers, R.N., was that brave Lieutenant William Rivers, R.N., who, as a midshipman in the *Victory* at Trafalgar, was severely wounded in the mouth and had his left leg shot away at the very beginning of the action, in defence of Nelson or in trying to avenge the latter's mortal wound. So at least runs the family tradition, also according to which Nelson's last words to his surgeon were "Take care of young Rivers." A maternal uncle of Rivers was Dr. James Hunt, who in 1863 founded and was the first President of the Anthropological Society, a precursor of the Royal Anthropological Institute, and from 1863 to 1866 at the meetings of this Association strove to obtain that recognition for anthropology as a distinct Subsection or Section which was successfully won for psychology by his nephew, who presided over us at the Bournemouth meeting in 1919, when we were merely a Subsection of Physiology.

Our "young Rivers" gave his first lecture at the age of twelve, at a debating society of his father's pupils. Its subject was "Monkeys." He was educated first at a preparatory school at Brighton, and from 1877 to 1880 at Tonbridge School. Thence he had hoped to proceed to Cambridge; but a severe attack of enteric fever compelled him to take a year's rest, and thus prevented him from competing for an entrance scholarship at that University. He matriculated instead in the University of London, and entered St. Bartholomew's Hospital in 1882, sharing the intention of one of his father's pupils of becoming an Army doctor. This idea, however, he soon relinquished; but, like his desire to go to Cambridge, it was to be realised later in life.[2]

When he took his degree of Bachelor of Medicine in 1886 he was accounted the youngest Bachelor ever known at his hospital. Two years later he graduated as Doctor of Medicine, and he spent these two and the two following years in resident appointments at Chichester (1888) and at St. Bartholomew's (1889) hospitals, in a brief period of private medical practice (1890), and in travelling as ship's surgeon to America and Japan (1887), the first of numerous subsequent voyages.

In 1892 he spent the spring and early summer at Jena, attending the lectures of Eucken, Ziehen, Binswanger, and others. In a diary kept by him during this visit to Germany the following sentence occurs: "I have during the last few weeks come to the conclusion that I should go in for insanity when I return to England and work as much as possible at psychology." Accordingly, in the same year he became clinical assistant at the Bethlem Royal Hospital, and in 1893 he assisted G. H. Savage in his lectures on mental

[1] From the presidential address delivered to Section J (Psychology) of the British Association at Hull on Sept. 11.

[2] For many of the above details of Rivers's early life and antecedents I am indebted to his sister, Miss K. E. Rivers.

diseases at Guy's Hospital, laying special stress on their psychological aspect. Meanwhile, at Cambridge, Michael Foster was seeking some one who would give instruction there in the physiology of the sense organs, McKendrick having, as examiner in physiology, recently complained of the inadequate training of the Cambridge students in this branch of the subject. Foster's choice fell on Rivers, and in 1893 he invited him to the University for this purpose. Rivers went to Germany for a short period of study under Professor Krapelin, then of Heidelberg, whose brilliant analysis of the work curve and careful investigations into the effects of drugs on bodily and mental work had aroused his intense interest. At Cambridge he set himself to plan one of the earliest systematic practical courses in experimental psychology in the world, certainly the first in this country. In 1897 he was officially recognised by the University, being elected to the newly established lectureship in physiological and experimental psychology. But the welcome and encouragement he received from cognate branches of study at Cambridge could scarcely be called embarrassing. Even to-day practical work is not deemed essential for Cambridge honours candidates in elementary psychology; psychology is not admitted among the subjects of the Natural Sciences Tripos; and no provision is made for teaching the subject at Cambridge to medical students. Rivers first turned his attention principally to the study of colour vision and visual space perception. Between 1893 and 1901 he published experimental papers "On Binocular Colour-mixture" (Proc. Camb. Philosoph. Soc., vol. viii., pp. 273-77), on "The Photometry of Coloured Papers" (*Jour. of Physiol.*, vol. xxii., pp. 137-45), and "On Erythropsia" (Trans. Ophthal. Soc., London, vol. xxi., pp. 296-305), and until 1908 he was immersed in the task of mastering the entire literature of past experimental work on vision, the outcome of which was published in 1900 as an article in the second volume of the important "Text-book of Physiology," edited by Sir Edward Sharpey Schafer. This exhaustive article of 123 pages on vision by Rivers is still regarded as the most accurate and careful account of the whole subject in the English language.

In 1896 Rivers published an important paper "On the Apparent Size of Objects" (*Mind*, N.S., vol. v., pp. 71-80), in which he described his investigations into the effects of atropin and eserin on the size of seen objects. He distinguished two kinds of micropsia which had hitherto been confused—micropsia at the fixation-point due to irradiation, and micropsia beyond the fixation-point, which is of special psychological importance. Rivers came to the interesting conclusion that the mere effort to carry out a movement of accommodation may produce the same micropsia as when that effort is actually followed by movement. In other words, an illusion of size may be dependent solely on central factors. His later work, in conjunction with Prof. Dawes Hicks, on "The Illusion of Compared Horizontal and Vertical Lines," which was published in 1908 (*Brit. Jour. of Psychol.*, vol. ii., pp. 241-60), led him to trace this illusion to origins still less motor in nature. Here horizontal and vertical lines were compared under tachistoscopic and under prolonged exposure. The amount of the illusion was found to be approximately the same for tachistosc as for prolonged exposure of the lines, but in the for the judgment was more definite and less hesitating- other words, more naive, more purely sensory, n "physiological"—than in prolonged exposure. though this result is not inconsistent with the view t visual space perception depends *for its genesis* on movement, it compels us to admit that visual sp perception, *once acquired*, can occur in the absence eye movement; or, in more general language, t changes in consciousness, originally arising in connex with muscular activity, may occur later in the abse of that activity. The provision of experime evidence in favour of so fundamental and wide-reach a view is obviously of the greatest importance.

In 1898, in which year he was given the degree Hon. M.A. at Cambridge, Rivers took a fresh path his varied career by accepting Dr. A. C. Hadd invitation to join the Cambridge Anthropolog Expedition to the Torres Straits. This was the f expedition in which systematic work was carried in the ethnological application of the methods a apparatus of experimental psychology. His form pupils, Prof. W. McDougall and I, assisted Rivers this new field. Rivers interested himself especia in investigating the vision of the natives—their vis acuity, then colour vision, their colour nomenclatu and their susceptibility to certain visual geome illusions. He continued to carry out psycholog work of the same comparative ethnological charac after his return from the Torres Straits in Scotla (where he and I sought comparative data), during visit to Egypt in the winter of 1900, and from 190 in his expedition to the Todas of Southern In His psychological investigations among the Tor Straits islanders, Egyptians and Todas (Reports of Cambridge Anthrop. Exped. to Torres Straits, vol. Pt. I., pp. 1-132; *Jour. of Anthrop. Inst.*, vol. xx pp. 229-47; *Brit. Jour. of Psychol.*, vol. i., pp. 321- will ever stand as models of precise, methodical obser tions in the field of ethnological psychology. Nowh does he disclose more clearly the admirably scient bent of his mind—his insistence on scientific procedu his delight in scientific analysis, and his facility adapting scientific methods to novel experimen conditions. He reached the conclusion that no su stantial difference exists between the visual acuity civilised and uncivilised peoples, and that the lat show a very definite diminution in sensibility to bl which, as he suggested, is perhaps attributable to t higher macular pigmentation among coloured peopl He observed a generally defective nomenclature f blue, green, and brown among primitive peoples, bo white and coloured, and large differences in t frequency of colour-blindness among the differe uncivilised peoples whom he examined. In his wo on visual illusions he found that the vertical-horizont line illusion was more marked, while the Muller-Ly illusion was less marked, among uncivilised than amo civilised communities; and he concluded that t former illusion was therefore dependent rather physiological, the latter rather on psychological facto the former being counteracted, the latter being favoure by previous experience, *e.g.* of drawing lines or apprehending complex figures as wholes.

In 1903, the year after his return from the Todas, and the year of his election to a Fellowship at St. John's College, Rivers began an investigation, continued for five years, with Dr. Henry Head, in which the latter, certain sensory nerves of whose arm had been experimentally divided, acted as subject, and Rivers acted as experimenter, applying various stimuli to the arm and recording the phenomena of returning cutaneous sensibility. The exact interpretation of this "Human Experiment in Nerve Division," published at length in 1908 (*Brain*, vol. xxxi., pp. 323-450), has been disputed by subsequent workers, whose divergent results, however, are at least partly due to their employment of different methods of procedure. Head's experiment has never been identically repeated, and until this has been done we are probably safe in trusting to the results reached by the imaginative genius and the cautious critical insight of this rare combination of investigators.

While working upon Head's arm, Rivers's indomitable activity led him to simultaneous occupation in other fields. In 1904 he assisted Prof. James Ward to found and to edit the *British Journal of Psychology*, and in that year he also received an invitation to deliver the Croonian Lectures in 1906 at the Royal College of Physicians, of which in 1899 he had been elected a Fellow. The study of drug effects had long interested him. So, reverting to the work he had done under Kraepelin many years previously, he chose as his subject for the Croonian Lectures, "The Influence of Alcohol and other Drugs on Fatigue" (Arnold, 1908). But although he utilised Kraepelin's ergograph and many of Kraepelin's methods, Rivers's *flair* for discovering previous "faulty methods of investigation" and his devotion to scientific methods and accuracy could not fail to advance the subject. Of no one may it be more truly said than of him,—*nihil tetigit quod non ornavit*. He felt instinctively that many of the supposed effects of alcohol were really due to the suggestion, interest, excitement or sensory stimulation accompanying the taking of the drug. Accordingly he disguised the drug, and prepared a control mixture which was indistinguishable from it. On certain days the drug mixture was taken, on other days the control mixture was taken, the subject never knowing which he was drinking. He found that the sudden cessation of all tea and coffee necessary for the study of the effects of caffeine induced a loss of energy, and that other mental disturbance might occur through giving up all forms of alcoholic drink. Therefore most of his experiments were carried out more than twelve months after the taking of these drinks had been discontinued. Instead of recording a single ergogram Rivers took several sets of ergograms each day, each set consisting usually of six ergograms taken at intervals of two minutes, and separated from the next set by an interval of thirty or sixty minutes. He arranged that the drug mixture or the control mixture should be taken after obtaining the first set of ergograms, which served as a standard wherewith subsequent sets on the same day might be compared. He worked with Mr. Webber on alcohol and caffeine, and was followed by the similar work of Dr. P. C. V. Jones in 1908 on strychnine, and of Dr. J. G. Slade in 1909 on Liebig extract.

With these vast improvements in method Rivers failed to confirm the conclusions of nearly all earlier investigators on the effects of from 5 to 20 c.c. of absolute alcohol on muscular work. His results with these doses, alike for muscular and mental work, were mainly negative, and indeed with larger doses (40 c.c.) were variable and inconclusive, although an equivalent quantity of whisky gave an immediate increase of muscular work, a result which strongly suggests the influence of sensory stimulation rather than the direct effect of the drug on the central nervous system or on the muscular tissues. Rivers concluded that alcohol may in some conditions favourably act on muscular work by increasing pleasurable emotion and by dulling sensations of fatigue, but that probably its most important effect is to depress higher control, thus tending to increase muscular and to diminish mental efficiency.

From the concluding passages of these Croonian Lectures the following sentences may be aptly cited: "The branch of psychology in which I am chiefly interested is that to which the name of individual psychology is usually given. It is that branch of psychology which deals with the differences in the mental constitutions of different peoples, and by an extension of the term to the differences which characterise the members of different races. . . . These experiments leave little doubt that variations in the actions of drugs on different persons may have their basis in deep-seated physiological variations, and I believe that the study of these variations of susceptibility may do more than perhaps any other line of work to enable us to understand the nature of temperament and the relation between the mental and physical characters which form its two aspects." Throughout his life Rivers was steadfast to this biological standpoint, correlating the psychological with the physiological, and hoping to discover different mental levels corresponding to different neural levels.

Now we approach the last phase of Rivers's psychological work, the outcome of his war experiences. In 1907 he had given up his University teaching in experimental psychology; for six years before the war he had published nothing of psychological or physiological interest. This was a period in which Rivers devoted himself wholly to the ethnology and sociology of primitive peoples. The outbreak of war found him for the second time visiting Melanesia for ethnological field work. Failing at first to get war work on his return to England, Rivers set himself to prepare the Fitzpatrick Lectures on "Medicine, Magic and Religion," which he had been invited to deliver to the Royal College of Physicians of London in 1915 and 1916. In 1915 his psychological and ethnological researches were recognised by the award to him of a Royal Medal by the Royal Society, of which he had been elected a Fellow in 1908. In July 1915 he went as medical officer to the Maghull War Hospital, near Liverpool, and in 1916 to the Craiglockhart War Hospital, Edinburgh, receiving a commission in the R.A.M.C. In these hospitals he began the work on the psychoneuroses that led him to his studies of the unconscious and of dreams, which resulted in his well-known book, "Instinct and the Unconscious," and in a practically completed volume on "Conflict and Dream," which is to be published posthumously. From 1917 he acted as consulting psychologist to the

Royal Air Force, being attached to the Central Hospital at Hampstead.

This period marks not merely a new phase in Rivers's work, but is also characterised by a distinct change in his personality and writings. In entering the Army and in investigating the psychoneuroses he was fulfilling the desires of his youth. Whether through the realisation of such long-discarded or suppressed wishes, or through other causes, *e.g.* the gratified desire of an opportunity for more sympathetic insight into the mental life of his fellows, he became another and a far happier man. Diffidence gave place to confidence, hesitation to certainty, reticence to outspokenness, a somewhat laboured literary style to one remarkable for its ease and charm. More than forty publications can be traced to these years, between 1916 and the date of his death It was a period in which his genius was released from its former shackles, in which intuition was less controlled by intellectual doubt, in which inspiration brought with it the usual accompaniment of emotional conviction—even an occasional impatience with those who failed to accept his point of view. But his honest, generous character remained unchanged to the last. Ever willing to devote himself unsparingly to a cause he believed right, or to give of his best to help a fellow-being in mental distress, he worked with an indomitable self-denying energy, won the gratitude and affection of numberless nerve-shattered soldier-patients, whom he treated with unsurpassed judgment and success, and attracted all kinds of people to this new aspect of psychology. Painters, poets, authors, artisans, all came to recognise the value of his work, to seek, to win, and to appreciate his sympathy and his friendship It was characteristic of his thoroughness that while attached to the Royal Air Force he took numerous flights, looping the loop and performing other trying evolutions in the air, so that he might gain adequate experience of flying and be able to treat his patients and to test candidates satisfactorily. He had the courage to defend much of Freud's new teaching at a time when it was carelessly condemned *in toto* by those in authority who were too ignorant or too incompetent to form any just opinion of its undoubted merits and undoubted defects. He was prepared to admit the importance of the conflict of social factors with the sexual instincts in certain psychoneuroses of civil life, but in the psychoneuroses of warfare and of occupations like mining he believed that the conflicting instincts were not sexual, but were the danger instincts, related to the instinct of self-preservation

Thus in the best sense of the term Rivers became a man of the world and no longer a man of the laboratory and of the study He found time to serve on the Medical Research Council's Air Medical Investigation Committee, on its Mental Disorders Committee, on its Miners' Nystagmus Committee, and on the Psychological Committee of its Industrial Fatigue Research Board He served on a committee, of ecclesiastical complexion, appointed to inquire into the new psychotherapy, and he had many close friends among the missionaries, to whom he gave and from whom he received assistance in the social and ethnological side of their work.

In 1919, in which year he received honorary degrees from the Universities of St. Andrews and Manchester,
he returned to Cambridge as Prælector in Natur
Sciences at St. John's College, and began immediate
to exercise a wonderful influence over the young
members of the University by his fascinating lecture
his "Sunday evenings," and above all by his eve
ready interest and sympathy. As he himself wrot
after the war work "which brought me into conta
with the real problems of life . . . I felt that it was in
possible for me to return to my life of detachment
And when a few months before his death he was i
vited by the Labour Party to a still more public sphe
of work, namely, to become a Parliamentary candida
representing the University of London, once again l
gave himself unsparingly. He wrote at the tim
"To one whose life has been passed in scientific researc
and education the prospect of entering practical politi
can be no light matter. But the times are so ominou
the outlook both for our own country and the world
black, that if others think I can be of service in politic
life I cannot refuse." On several occasions subs
quently he addressed interested London audiences, co
sisting largely of his supporters, on the relations b
tween psychology and politics. It was one of the
very lectures—on the herd instinct—at which it ha
pened that I took the chair, which was to have form
the basis of his Presidential Address to you here to-da

Rivers's views on the so-called herd instinct were t
natural outcome of those which he had put forwa
during the preceding five years and collected togeth
in his "Instinct and the Unconscious" His aim
writing this book was, as he says, "to provide
biological theory for the psychoneuroses," to view t
psychological from the physiological standpoint. I
maintained that an exact correspondence holds l
tween the inhibition of the physiologist and the r
pression of the psychologist. He regarded ment
disorders as mainly dependent on the coming to t
surface of older activities which had been previous
controlled or suppressed by the later products of evol
tion. Here Rivers went beyond adopting Hughlin
Jackson's celebrated explanation of the phenomena
nervous diseases as arising largely from the release
lower-level activities from higher-level controls I
further supposed that these lower-level activities rep
sent earlier racial activities held more or less in ab
ance by activities later acquired. This conception
derived from his work with Henry Head on cutane
sensibility. Rivers could see but "two chief pos
bilities" of interpreting the phenomena disclosed
the study of Head's arm. Either epicritic sensibil
is protopathic sensibility in greater perfection, or e
protopathic sensibility and epicritic sensibility rep
sent two distinct stages in the development of t
nervous system Failing to see any other explanati
he adopted the second of these alternatives. He su
posed that at some period of evolution, when epicri
sensibility, with its generally surface distribution,
high degree of discrimination, and its power of accur
localisation, made its appearance, the previously ex
ing protopathic sensibility, with its punctate distri
tion, its "all-or-nothing" character, and its bro
radiating localisation, became in part inhibited
"suppressed," in part blended or "fused" with t
newly acquired sensibility so as to form a use
product. He supposed that the suppressed porti

persisted in a condition of unconscious existence, and he emphasised the biological importance of suppression. He considered at first that the protopathic sensibility "has all the characters we associate with instinct," whereas the later epicritic sensibility has the characters of intelligence or reason. So he came to hold that instinct "led the animal kingdom a certain distance in the line of progress," whereupon "a new development began on different lines," "starting a new path, developing a new mechanism which utilised such portions of the old as suited its purpose."

Evolutio per saltus was thus the keynote of Rivers's views on mental development. Just as the experience of the caterpillar or tadpole is for the most part suppressed in the experience of the butterfly or frog, so instinctive reactions tend to be suppressed in intelligent experience whenever the immediate and unmodifiable nature of one becomes incompatible with the diametrically opposite characters of the other. Just as parts of the protopathic fuse with the later acquired epicritic sensibility, so parts of our early experience, of which other parts are suppressed, fuse with later experience in affecting adult character. "Experience," he explained, "becomes unconscious because instinct and intelligence run on different lines and are in many respects incompatible with one another."

From his point of view Rivers was naturally led, wherever possible, to interpret abnormal mental conditions in terms of regression to more primitive, hitherto suppressed activities. He held that the hysterias are essentially "substitution neuroses," connected with and modified by the gregarious instincts, and are primarily due to a regression to the primitive instinctive danger reaction of immobility, greatly modified by suggestion. So, too, he held that the anxiety neuroses, which are for him essentially "repression neuroses," also show regression, though less complete, in the strength and frequency of emotional reaction, in the failure during states of phantasy to appreciate reality, in the reversion to the nightmares, and especially the terrifying animal dreams, characteristic of childhood, in the occurrence of compulsory acts, in the desire for solitude, etc. He criticised Freud's conception of the censorship, substituting in place of that anthropomorphically-coloured sociological parallel the physiological and non-teleological conception of regression.

We are now in a position to examine Rivers's treatment of the gregarious behaviour of animal and human life, on which he was still engaged at the time of his death. In the gregarious instinct he recognised a cognitive aspect which he termed "intuition," an affective aspect which he termed "sympathy," and a motor aspect which he termed "mimesis." He used "mimesis" for the process of imitation so far as it was unwitting; "sympathy" he regarded as always unwitting. "Intuition" he defined as the process whereby one person is unwittingly influenced by another's cognitive activity. But I feel sure that the term "unwittingly" is not to be considered here as equivalent to "telepathically." All that Rivers meant was that the person is influenced by certain stimuli without appreciating their nature and meaning. He preferred to employ the term "suggestion" as covering all the processes by which one mind acts on or is acted on by another unwittingly. He supposed that in the course of mental evolution epicritic characters displaced the early protopathic characters of instinctive behaviour owing to the incidence of gregarious life, especially among insects, and owing to the appearance and development of intelligence, especially in man. The suggestion inherent in gregarious behaviour implies some gradation of mental and bodily activity, an instinctive and unwitting discrimination distinct from the witting discrimination of intelligence.

Were he here to-day Rivers would have carried this conception of the evolution of gregarious life still further by distinguishing between the more lowly leaderless herd and the herd which has acquired a definite leader. He would have traced the development of the new affect of submission and of the new behaviour of obedience to the leader, and he would doubtless have accredited the leader with the higher affects of superiority and felt prestige, with the higher cognition that comes of intuitive foresight, and with the higher behaviour of intuitive adaptation, initiative, and command. I expect, too, that he would have sketched the development of still later forms of social activity, complicated by the interaction and combination of intellectual and instinctive processes—the witting deliberations and decisions on the part of the leader, and the intellectual understanding of the reasons for their confidence in him and for their appropriate behaviour on the part of those who are led.

But it would be idle further to speculate on the ideas of which we have been robbed by Rivers's untimely death. Let us rather console ourselves with the vast amount of valuable and suggestive material which he has left behind and with the stimulating memories of one who, despite the fact that his health was never robust, devoted himself unsparingly to scientific work and to the claims of any deserving human beings or of any deserving humane cause that were made upon him. There are, no doubt, some who believe that Rivers's earlier experimental psychological work—on vision, on the effects of drugs, and on cutaneous sensibility—is likely to be more lasting than his later speculations on the nature of instinct, the unconscious, dreams, and the psychoneuroses. No one can doubt the scientific permanence of his investigations in the laboratory or in the field; they are a standing monument of thoroughness and accuracy combined with criticism and genius. But even those who hesitate to suppose that at some definite period in mental evolution intelligence suddenly made its appearance and was grafted on to instinct, or that epicritic sensibility was suddenly added to a mental life which had before enjoyed only protopathic sensibility—even those who may not see eye to eye with Rivers on these and other fundamental views on which much of his later work rested, will be foremost in recognising the extraordinary stimulating, suggestive, and fruitful character of all that he poured forth with such astounding speed and profusion during the closing years of his life. Above all, we mourn a teacher who was not merely a man of science devoted to abstract problems, but who realised the value of and took a keen delight in applying the knowledge gained in his special subject to more real and living problems of a more concrete, practical, everyday character. Rivers's careful methods of investigating

cutaneous sensibility and the *rationale* of his successful treatment of the psychoneuroses were directly due to his psychological training. So, too, his epoch-making discoveries and his views in the field of anthropology on the spread and conflict of cultures were largely due to the application of that training. Shortly before his death he was developing, as a committee member of the Industrial Fatigue Research Board, an intense interest in that youngest application of psychology, namely, to the improvement of human conditions in industrial and commercial work by the methods of experimental psychology applied to fatigue study, motion study, and vocational selection.

Unhappily, men of such wide sympathies and understanding as Rivers, combined with a devotion to scientific work, are rare. He himself recognised that "specialisation has . . . in recent years reached such a pitch that it has become a serious evil. There is even a tendency," he rightly said, "to regard with suspicion one who betrays the possession of knowledge or attainments outside a narrow circle of interests" (*Brit. Jour. of Psychol.*, vol. x., p. 184). Let his life, his wisdom, his wide interests, sympathies and attainments, and the generosity and honesty of his character, be an example to us in the common object of our meeting this week—the advancement of science.

Obituary.

PROF. F. D. BROWN.

WE regret to announce the death, on August 2, at Remuera, New Zealand, of emeritus professor Frederick Douglas Brown, at the age of seventy years. Prof. Brown began the study of chemistry in 1870, under Dr. Matthiessen, at St. Bartholomew's Hospital. On the death of Dr. Matthiessen, he continued his studies at the Royal College of Science, South Kensington and afterwards in Leipzig. On his return to England about 1876, he began research work at the London Institution with Prof. Armstrong, whom he had known at St. Bartholomew's. He then spent some time in Prof. Guthrie's laboratory and afterwards in the University Laboratory, Oxford. During this period, he was concerned in the teaching of chemistry at Cheltenham and Clifton Colleges and he also supervised the construction of the chemical laboratories in University College, Nottingham.

In 1883 Brown was appointed professor of chemistry and physics in Auckland University College, a post he held until 1914, when he came to England; but he was so upset by the conditions of the war, especially the bombing, that he gave up his intention of settling here and, in 1918, returned to the quiet of New Zealand. He did the greatest possible service to the cause of scientific education in New Zealand, where he was generally held in high esteem.

A man of original and independent, aristocratic mind but entirely unobtrusive though charming manner, firm and clear in his convictions and with a specially developed sense of accuracy and thoroughness, Brown's scientific work was of a classic character, though through force of circumstances it could not be large in amount; however, he not only made the best of the material that was at his disposal in Auckland but was also successful in inspiring those who studied under him with his own high conceptions of scientific duty. The work by which he is best known probably is that relating to fractional distillation, a subject on which he was an authority in early days; he also paid much attention to the cyanide process of extracting gold.

PROF. F. T. TROUTON, F.R.S.

AT Trinity College, Dublin, in the 'eighties of last century, there assembled under Prof. FitzGerald a small band of enthusiastic physicists of great ability and originality, brought together by a common admiration and affection for their chief. Names which will always be connected with this brilliant school of physics are Joly, Preston, and Trouton. FitzGerald himself did not live to be fifty, Preston died in his fortieth year, and now, to the great grief of all those who ever knew him, Trouton has left us at the age of fifty-eight, after having been kept by illness for the past ten years from the researches he loved.

Trouton was born in Dublin in November 1863, the son of a family well known in that city. As a student at Trinity College he gave early evidence of that versatility and quickness of grasp which characterised his scientific career. He studied both engineering and the physical sciences, and before graduating had already on one hand taken a leading part in surveying for a railway, and on the other enunciated that connexion between latent heat and molecular weight which is known as Trouton's Law.[1] He closed a brilliant undergraduate career by taking degrees in engineering and science at the same time, being awarded the coveted Large Gold Medal, rarely bestowed for science. He at once became assistant to the professor of physics at Trinity College, and until FitzGerald's death in 1901 he remained the cherished colleague and intimate friend of that great man. They carried out in collaboration many experiments, including an important series confirming, to a high degree of accuracy, Ohm's law for electrolytes. Trouton never spoke of FitzGerald without emotion characteristic of his generous nature.

The Dublin school was immediately struck with the importance of Hertz's experiments on electromagnetic waves, which were published in 1887 and 1888, and Trouton was one of the first to repeat them and to carry out original work on the subject. He settled the long-disputed question as to the relation between the direction of the vibration in the wave-front of an electromagnetic (light) wave and the plane of polarisation, by showing that the electric vector is normal to, and the magnetic vector in, the plane of polarisation. He demonstrated many analogies with optical experiments by suitably increasing the size of the apparatus to correspond to the great wave-length of the Hertzian waves—thus a wall built of bricks of paraffin wax was used to replace the soap film of ordinary light experiments. Trouton's work did much to establish the common electromagnetic nature of ordinary light and of Hertzian waves.

[1] If M be the molecular weight, L the latent heat, T the absolute temperature, then ML/T is constant.

FitzGerald was deeply interested in the question of the possibility of detecting the earth's motion through the æther, and Trouton eagerly took up a suggestion to investigate the mechanical effect of charging a condenser moving in the plane of its plates through the æther. The experiment, which is well known to all students of relativity, gave a negative result. It was in 1902, just after this research, that Trouton was appointed to the Quain professorship of physics at University College, London. He had at the time been for some years a Fellow of the Royal Society. His first work here was to repeat, with Noble, the condenser experiment in an improved form. Later he devised another experiment, designed to detect the FitzGerald shrinkage, which consisted in comparing the electrical resistance of a wire when moving in and across the æther stream. This was carried out in collaboration with Mr. (now Prof.) A. O. Rankine, and led to a negative result. The results of these experiments are in accord with the theory of relativity, for which they offer important evidence.

Trouton carried out researches in a variety of directions, including some on the viscosity of solids, and others on the condensation of water vapour on different surfaces, the latter of which led to the discovery of an interesting analogy to the James Thomson portion of an isothermal. His last work was on the adsorption of dye-stuffs on sand at various concentrations, and gave results of an intriguing nature which cannot be described here. It was while engaged on these investigations in 1912 that Trouton was attacked by a severe illness. He recovered from a prolonged prostration sufficiently for it to be hoped that he would be able to attend the meeting of the British Association in Australia in 1914, and he was elected president of Section A for that meeting. He prepared his presidential address, but was unable to travel, as an early operation was advised. It was held to be partly successful, but he never walked again. When he resigned his professorship at University College he received the title of emeritus professor.

The investigation of newly discovered or of neglected phenomena had a great fascination for Trouton; he was always breaking fresh ground, and had little inclination for working over subjects on which many investigations had been carried out—"pouring water on a drowned rat," as he characteristically expressed it. In daily life he was a man of great charm and sincerity; his wit, his buoyancy, and his whimsical and incisive phrases were a constant delight. He never lost an opportunity of helping a student or colleague, and his kindliness was evident in all his actions, a kindliness which had its roots in strength, and not weakness, of character. When in the prime of life he was struck down by a cruel and lingering illness he carried his cheerfulness to his couch, and would receive visitors with something like the old twinkle in his eye. Fate did not spare him; he lost two hopeful and beloved sons in the war, and saw all hope of recovery slowly pass from him. He died peacefully at his house at Downe on September 21, and, although his death was not unexpected, it brought to his friends a distress no less poignant for that.

E. N. da C. A.

We regret to see announcements of the following deaths:—Prof. Arthur Mayer, formerly director of the Botanic Garden at Marburg, at the age of seventy-two years; Dr. William Kellner, formerly chemist to the War Department, aged eighty-two, on September 25; Prof. J. P. Kuenen, of the University of Leyden, aged fifty-five; on September 27, Mr. C. Michie Smith, late director of the Kodaikanal and Madras Observatories; and on September 28, Major-General James Waterhouse, from 1866 to 1897 Assistant Surveyor-General in charge of photographic operations in the Surveyor-General's Office, Calcutta, at the age of eighty years.

Current Topics and Events.

The hundredth anniversary of the birth of Mendel was celebrated in Brünn on September 23 last. The Government of Czecho-Slovakia placed generous funds at the disposal of a local committee, which arranged the centenary celebrations with the liberality and efficiency that we have learnt to expect from the new Czecho-Slovakian state. Credit is especially due to the committee for having made the centenary an occasion for bringing together, for the first time since the war, geneticists of all lands, the visitors comprising representatives of America, Austria, Denmark, England, Finland, Germany, Holland, India, Japan, Jugoslavia, Norway, Poland, Sweden, and Switzerland. The official proceedings opened with a visit to the monastery in which Mendel had lived, and to the adjoining garden in which he made his experiments. Wreaths were laid before the monument of Mendel which was erected in 1910, and speeches were made by the chairman of the local Naturwissenschaftlicher Verein, by the official representative of the Government, by the Burgomeister, by Prof. Erwin Baur (Berlin), Prof. Chodat (Geneva), Prof. Němec (Prague), Mr. S. Pease (Cambridge), and Prof. Iltis (Brünn). At the luncheon which followed, the principal speaker was Prof. Wettstein (Vienna), who emphasised particularly the international significance of the event. Prof. C. B. Davenport (Washington) replied, and the official proceedings terminated with a speech by Prof. Richard Hertwig (Munich). In the evening, a special performance was given at the opera, to which the guests were invited. It was the first occasion in Brünn on which the works of Czech and German composers had appeared on the same programme, a matter locally of much comment and great importance. The next day an expedition to recently discovered and very remarkable caves in the Moravian Karst was arranged. It is to be hoped that the success of this gathering will encourage others to organise congresses that are international and not merely inter-allied, in order that the friendships and intercourse which the war destroyed may be once more built up.

A kindly function was fulfilled at the London School of Tropical Medicine on Monday evening of last week, September 25, before a company of friends of the School and the family, when the first mint of the new medal instituted in memory of Sir Patrick Manson was presented to his widow. Major-General Sir William Leishman, who made the presentation, explained that the medal was the sub-issue of a project by friends of Sir Patrick Manson to present to the School a portrait of its illustrious originator. As the result of an appeal for this purpose, subscriptions in excess of the actual requirements quickly came in from many parts of the world, accompanied by numerous very cordial tributes of approval. The portrait had been presented, and when all expenses had been met there still remained a balance which the committee of subscribers thought would find its most happily inspired application in a medal commemorative of Sir Patrick Manson's unique position in the history of tropical medicine. In a graceful speech Sir William Leishman alluded to the many ways whereby, outside the laboratory, quite as effectively as within it, a wife can further her husband's work, and said that it was with a full appreciation of the circumstances from this point of view, and not as a mere compliment, that the committee desired to offer the first-minted medal to Lady Manson.

M. Le Trocquer, Minister of Public Works, was present at tests on September 26, in connexion with the utilisation of tidal power at Aberwrach, near Brest. The scheme is to comprise a barrage 150 metres in length, which will permit of the storage in a tidal basin of from one to four million cubic metres of water, depending on the tidal range. Four turbines are to be installed, working both on the ebb and flow of the tide and capable of delivering 750-1200 h.p. These are coupled to alternators delivering current at 1500 volts. This station is to work in conjunction with a water-power station developing power from river-flow, and the latter is to be used to regularise the intermittent output from the tidal-power scheme. Should the results of this investigation prove satisfactory it is intended to develop a much larger scheme on the Rance, and, according to the *Times* of September 28, the minister expressed the opinion that this would enable electrical energy to be supplied to the whole of Western France.

We learn from the *Chemical Age* that the chairman of the Allied Chemical and Dye Corporation of New York has offered, through the American Chemical Society, an annual prize of 25,000 dollars "to reward the chemist, residing in the United States, who in the opinion of a properly constituted jury has contributed most to the benefit of the science and of the world." In communicating the offer, the chairman of the Corporation writes: "Realising, as we do, the enormous influence which chemists working in all the fields of that science will have on the welfare of the world, we desire by this prize so to encourage the workers that even larger benefits should accrue than those which have already placed the world under such a debt of gratitude to the profession." Last week reference was made in our columns (p. 466) to numerous substantial gifts by industrial concerns in Germany to German universities to assist in the teaching of scientific subjects, particularly chemistry. Thus in both the United States and in Germany, commercial men and manufacturers are showing their appreciation of the value of what may be termed, research in pure science.

According to *Science*, the American Medical Association has agreed to co-operate with the directors of the Gorgas Memorial Institute of Tropical and Preventive Medicine in establishing the institute, and a committee of the Association has issued an appeal for subscriptions. The committee is agreed that the most suitable memorial to Major-General William C. Gorgas would be such an institute, and considers that no more appropriate place than Panama City, where General Gorgas's great work in stemming tropical diseases was done, could have been selected. The Government of Panama has given the Santo Tomas Hospital, and also the land on which it is proposed to build the laboratories and departments for research, to constitute the memorial institute; Dr. R. P. Strong has been appointed scientific director. It is also intended that a Gorgas School of Sanitation shall be established in Tuscaloosa, Alabama, for training public health workers and sanitary engineers especially for work in the Southern States of America. An endowment of some 1,300,000*l.* will be necessary to carry out in full the proposed memorial.

Prof. Santiago Ramón y Cajal has retired from the chair of histology and pathological anatomy in the University of Madrid. This distinguished man of science, who is a Foreign Member of the Royal Society, has been the recipient of numerous honours in Spain, including the Echegaray medal, presented to him in the Royal Academy of Sciences by the King of Spain. The Spanish Government has introduced a bill for the construction of a building for the Cajal Institute, constituted in 1920, which carries with it an appropriation of nearly 36,000*l.*, divided into four sums to be expended annually from 1922 to 1925 on the building designated as Cajal's Biological Institute; in addition, a grant of about 1700*l.* is to be provided for maintenance. The work of the institute will be directed by a board of trustees under the chairmanship of Cajal himself.

About a year ago the Chemical Society issued an appeal to its fellows to assist in the alleviation of distress among chemists and other scientific workers in Russia. Since then a sum of more than 210*l.* has been received, and about 170*l.* of it was devoted to the purchase of clothing, which has been distributed among men of science in Ekaterinburg, Moscow, and Petrograd. In addition, three cases containing clothing and books have been sent to the latter two cities. It is now known definitely that the packages have reached those for whom they were intended, so that the possibility of gifts going astray need no longer deter possible subscribers. There is every reason to fear that during the coming winter distress will be as acute as it was a year ago, and the Chemical

Society appeals to all British chemists to give assistance. Gifts of money, clothing, books, and recent chemical literature should be addressed to the Assistant Secretary, The Chemical Society, Burlington House, Piccadilly, W.1.

In his presidential address delivered before the Royal Anthropological Institute (vol. lii. part 1) the late Dr. Rivers laid special stress on the difficulties which impede research by the excessive cost of printing and book production, and the rise in rent and taxes for accommodation used by scientific societies. He pointed out how closely all the branches of anthropological work—physical, sociological, archæological, psychological—are connected. Numerous societies, like the Royal Asiatic, African, and Japan societies, with the Hellenic and Roman societies and that specially devoted to folk-lore, should become more closely allied than is the case at present. The provision of a common building with adequate accommodation for a lecture room, library, and secretarial quarters would do much to reduce expenditure and promote efficiency. The leading society, the Royal Anthropological Institute, is most inadequately housed, while the Folk-lore Society has no headquarters of its own. It is quite time that an earnest effort was made to reorganise the work of these and similar societies. Individual jealousies and prejudices must be encountered, but the spirit of conciliation, reinforced by the difficulties of the present situation, should succeed in framing a scheme of co-operation.

In accordance with arrangements followed for many years past there is to be a series of meetings, generally on alternate Mondays at 5 P.M., at the Meteorological Office, South Kensington, for the informal discussion of important contributions to meteorological literature, especially in foreign and Colonial journals. The meetings will commence on Monday, October 16, when, as customary at the first meeting, the discussion will be opened by Sir Napier Shaw. The subject is a paper by V. Bjerknes "On the dynamics of the circular vortex with application to the atmosphere and atmospheric vortex of wave motions."

The third of the series of lectures, under the auspices of the Institute of Physics, on physics and the physicist in industry will be given by Mr. Clifford C. Paterson, who will take as his subject, "The Physicist in Electrical Engineering." The lecture will be delivered on Wednesday October 18 at 6 P.M. at the Institution of Electrical Engineers, Victoria Embankment, W.C.2.

On the recommendation of the committee of management of *Science Abstracts*, the council of the Institution of Electrical Engineers has appointed Mr. W. R. Cooper to be editor of the publication in succession to the late Mr. L. H. Walter. Mr. Cooper was acting editor of *Science Abstracts* in the first year of its existence, 1898, and afterwards was editor from 1899 to 1901.

The Home Secretary gives notice that summer time will cease this year at 3.0 A.M. (summer time) in the morning of Sunday, October 8, when clocks will be put back to 2 A.M. The shorter period of summer time prescribed by the Summer Time Act, 1922, does not operate this year.

Our Astronomical Column.

October Meteor Showers.—The month of October is usually one of the best periods for observing meteors. The moon will interfere this year in the early part of the month, but during the last half, observations may be satisfactorily made. The chief shower generally visible falls in the third week of the month, and is directed from a radiant point at 91° +15° on the north-eastern borders of Orion. There is also a strong shower which supplies slow and often brilliant meteors at about the same time as the Orionids, but this radiant in the eastern region of Aries at 42° +21° appears to be visible for a long period, and is also seen in the months of November and December. The Taurids often form a conspicuous display towards the end of October, but they are generally more abundant in November than at any other time of the year. The latter shower yields meteors very similar to the Arietids, and fireballs are frequently intermingled with the smaller members of the stream. The chief radiant is at 64° +22°; it is difficult to define the date of maximum, but it usually occurs between November 20 and 23.

The meteoric activity of October is not confined to a few systems, for a very large number, certainly several hundreds, may be recognised. They are, however, for the most part feeble, like the majority of the systems which are distributed over the firmament.

Parallaxes of 22 Cepheids.—Dr. Harlow Shapley's estimates of the distances of the globular clusters rest largely on the assumed absolute magnitudes of B stars and Cepheid variables. It is very desirable to have as many independent determinations as possible of the distances of the brighter Cepheids, in order to check their assumed absolute magnitudes. Dr. S. A. Mitchell has determined the trigonometrical parallaxes of 22 of them, and publishes the results in the *Observatory* for September. Perhaps the most doubtful point is the mean parallax of the comparison stars; they are of the 10th magnitude, assumed parallax 0″·005. The deduced absolute parallaxes for the Cepheids range from +0″·046 (ρ Cassiopeiae) to −0″·018 (61 Cygni). There are only 3 negative parallaxes. The mean parallax agrees very closely with the mean of the spectroscopic values; rejecting ρ Cassiopeiae, the mean difference, Mitchell *minus* spectroscopic, is only 0″·0003. It is concluded that the latter are very accurate.

Nova T Coronae (1866).—This Nova is exceptional in two ways. It is the only Nova that was a catalogued star before the outburst (BD +26° 2765), and it is much farther from the Galaxy than other Novae. Mr. K. Lundmark investigates its proper motion and parallax in Publ. Ast. Soc. Pacific, August 1922. The proper motion is given as 0″·012 annually, towards position angle 41°; from this the parallax is inferred to be 0″·0010, while the spectroscopic parallax is 0″·0014. Adopting 0″·0013, its present absolute magnitude is +0·2, while that at the outburst was −7·4, in good agreement with the maximum value for other Novae. The star is an M giant, and apparently is now in the same condition as before the outburst. If the above parallax is near the truth, the star is considerably more remote than Nova Persei (1901) or Nova Aquilae (1918).

Research Items.

THE STATUE OF SOPHOCLES IN THE LATERAN MUSEUM.—The chief glory of the Lateran Museum is the great statue usually supposed to be that of the poet Sophocles. This identification is disputed by Mr. Théodore Reinach (Journal of the Hellenic Society, vol. xlii. Part 1), who, after a full discussion of the evidence, identifies it with the famous statue of Solon of Salamis, dating about 301 B.C., the work of the artist Kephisodotus, whose son and pupil seems to have been Praxiteles. This new work by a great master thus stands out as the herald of a new dawn of art, the real link between the divine Phidias and the divine Praxiteles.

EXCAVATIONS AT THE SITE OF BETHSHEAN.—The town of Bethshean, afterwards, for some unexplained reason, known as Scythopolis, lay between the Little Hermon and Gilboa ranges, on a plain about three miles west of the Jordan. Permission to excavate the site by the University Museum, Philadelphia, having been granted by the Archaeological Department of Palestine, the work was started in 1921 under the superintendence of Mr. C. S. Fisher. Fortunately no Mahomedan tombs or other buildings on the mound interfere with the work of excavation. The stratification shows a continuous occupation of the site from Arab, Byzantine, and Classical times down to the early Semitic period. The results of the excavations, so far as they have proceeded, are described in the March issue of the *Museum Journal*. The most important discovery made is that of a large basalt stele with an Egyptian inscription of Sety I. (1313–1292 B.C.). When the lowest stratum is reached it is hoped that much light will be thrown on early Semitic life and religion.

BANTU THROWING-STONES AND BRASS.—In the Report of the South African Museum for 1921, Dr. Péringuey discusses some large rounded stones, perforated in the manner of the Bush *Kwe*, and weighing about 18 lb. He does not think that they could have been used to weight digging-sticks or as rolling mill-stones. With them were some stones, also perforated, but rather flat, with a sharp edge. These, it is said, were carried on a stick by the Bantu, and used for throwing at the legs of bucks. This explains the use of some heavy brass rings found in Swaziland, and the question arises whether the brass was made in that country or was imported. The Chief Regent of Swaziland says that the former was the case, and adds: "The process of separating was by melting the minerals and certain chemicals known to our ancient blacksmiths and founders. In the making of brass and other metals copper, lead, and zinc were used for the manufacture of bangles, etc., which were worn only by Royalties. The bangle in this form is known as Itusi, it is the form in which brass is kept, instead of making it into bars as the Europeans do." Specimens in the museum show that the Bantu had also a bronze industry, but the rarity of such objects is rather remarkable, and Dr. Péringuey suggests as the reason the very early supersession of bronze by iron in South Africa.

PHYSICAL NATURE OF VERSE.—A recent number of the *Wiener Medizinische Wochenschrift* reports a lecture at the University of Vienna by Prof. E. W. Scripture, of London and Hamburg, on recent researches in experimental phonetics. Speech is registered by physical means on a recording drum, and the resulting curves are analysed and measured under a microscope. One of the latest problems is that of the physical nature of verse. Verse is shown to be a continuous vocal gesture. There are no syllables, no feet, no measures, no possibility of such notions as iambus or trochee. The entire system of metre as taught in modern prosody is held to be a fantastic construction that has not the slightest relation to verse as actually spoken. Any attempt to fit it to verse or fit verse to it results in such monstrosities as some of the present corrections to the text of Shakespeare, with apologies for the bad verse he is supposed to have written. Verse, from a physical point of view, is shown to be a flow of speech energy with regularly recurring regions of greater density. The total of this energy can be treated as if condensed at certain points—centroids or centres of gravity. These centroids recur at regular intervals and give the effect of beats. This regular recurrence of centroids constitutes the whole of the system of verse. Another topic presented was the recent work on registering speech in nervous diseases. Three diseases—epilepsy, disseminated sclerosis, and general paralysis—show specific peculiarities in the records. A diagnosis thus becomes an automatic thing; the speech is registered, the curves are analysed and measured, and the result appears of itself.

THE SITE AND GROWTH OF LONDON.—The relation of topography and underlying structure to the growth of London are traced in some detail by Mr. C. E. M. Bromehead in a paper in the *Geographical Journal* for August. After describing the extent of alluvial and river gravels and the course of the Thames tributaries in the area now covered by London, Mr. Bromehead points out that the narrowness of the river and the approach by gravel banks from either side marked the present site of London Bridge as the lowest ford. Around this, especially on the better situated northern bank, the original London grew. The essentials of the site, in addition to the ford, were twin hills capped by water-bearing gravels separated by the valley of the Wall Brook, bounded on the west by the Fleet and on the east by the low ground of the Thames marshes. To the north was the forest area of the London clay, but the river gravels were comparatively bare. The early Roman camp, which was the earliest historic London, was on the east hill; on the west hill the brick earth was worked until the city grew over it. Mr. Bromehead traces the growth of London through Saxon times and up to the Great Fire in 1666. After that event London rapidly expanded. The limit of the gravels for a long time set a limit to building operations. Wells sunk through the gravel, seldom more than 25 ft. in thickness, were sure to tap water, but it was not realised till recent times that better supplies could be obtained beneath the clay at depths of 150 ft. and more. It was for this reason that the areas of bare London clay remained unoccupied until the advent of steam pumping and iron water mains. Once these difficulties of water supply were overcome, the clay areas were rapidly built over and outlying hamlets became linked up with London.

MEDIAN PROLIFICATION OF FLOWERS OF HEMEROCALLIS.—We learn from Dr. J. C. Costerus, of Hilversum, Holland, that he has observed numerous central floral prolifications in *Hemerocallis fulva* in gardens at Hilversum, in the botanic gardens at Amsterdam and Utrecht, and also at Twickenham in this country, during the past summer. Apparently the prolification resembled closely a "doubled" flower. Median prolification of flowers of Hemerocallis, although apparently rare, has been noted on

several occasions and is referred to in "Vegetable Teratology," by the late Dr Maxwell T. Masters. While it is difficult to suggest a reason for the phenomenon with any degree of certainty, it is probable that the condition may have been more prevalent than usual this year owing to the prolonged drought of 1921 and the early months of 1922, placing a check upon normal development, followed by a rush of vigorous growth brought about by the wet summer months. A check to growth followed by a sudden change to first-rate growing conditions often brings about fasciation, and the median prolification of flowers of Hemerocallis may be regarded in a rather similar light to fasciation.

LIFE-HISTORY OF THE NEUROPTEROUS INSECT ITHONE.—In the Bulletin of Entomological Research, vol. xiii. pt. 2, August 1922, Dr. R. J. Tillyard gives a very detailed account of the biology of *Ithone fusca*, an Australian moth-lacewing. It appears that the complete life-history occupies two years, and the eggs are laid in soft or sandy ground, each being rolled separately in the sand, which adheres to its sticky surface, forming a protective covering. The larvæ are very different from those of other Neuroptera Planipennia, being curved and more or less scarabæiform in their general features. There appear to be at least five instars instead of the usual three or four present in other members of the sub-order. The cocoon is spun from the anal end of the body, and the pupa is armed with large jaws for cutting a way out for the emergence of the imago. The larval food appears to be mainly scarabæid grubs, and Dr. Tillyard is so impressed with the value of Ithone in reducing the numbers of these organisms, that he has decided to test its capabilities as an aid to agriculture in New Zealand. Some 7000 fertile eggs of *Ithone fusca* have been introduced, and it remains to be seen whether the larvæ will succeed in establishing themselves under the new conditions, and serve as a help towards controlling the "grass-grubs." The latter are serious pests with but few natural enemies in New Zealand.

THE MAGNIFICENT SPIDER (*Dicrostichus magnificus*, Rainbow).—In the Proceedings of the Royal Society of Queensland (vol. xxxiii. 1921, pp. 91-98, pls. 7 and 8) Mr. H. A. Longman gives an interesting account of this very large and handsome spider. It appears that the creature constructs egg-cocoons of a more or less elongate-fusiform shape, each being suspended by a pedicel attached to a bush. Their total length measures from three to four inches with a maximum diameter of about one inch. The cocoon is double, one cocoon lying within the other, and between them is a loose packing of delicate silk. Within the inner cocoon are the eggs, which number more than 600, and, taking five cocoons as an average, each spider lays about 3000 eggs. After hatching, the young spiders climb up the surrounding leaves and spin fine threads. On the latter they are floated, or ballooned, through the air to start life on their own account. The author gives a detailed account of how this remarkable cocoon is spun by the parent, which, although skilful in this art, had neither the capacity nor inclination to mend a rent in it when it was torn by a cricket-like insect. The spider constructs no web for ensnaring prey, but shortly after sunset it hangs suspended from a horizontal line near its cocoons. From this slender bridge it spins a short filament which hangs downwards and terminates in a globule of viscid matter a little larger than the head of an ordinary pin. The filament is held out by one of the front legs, and, on the approach of an insect, the spider whirls it with surprising speed; this is undoubtedly the way in which it secures its prey. Mr. Longman has repeatedly found the spider sucking a common species of Noctuid moth which it captures in this manner.

IMPROVED RIVER DISCHARGE MEASUREMENTS.—In the measurement of river discharge special difficulties are encountered in the case of sluggish streams such as the Blue Nile at Soba during low water. In a report on "Investigations into the Improvement of River Discharge Measurement," Pt. II. (Government Press, Cairo), Mr. E. B. H. Wade gives the result of his experiments with an improved current meter for streams of this type. It is a helical current meter in which the helix is driven not by the stream but by an independent constant power. The effect of the stream is merely to increase or diminish the rate of the helix by an amount which serves as a measure of the stream's velocity. An instrument on these lines is being constructed by Messrs. Kent and Co. The distinctive feature of the model is that gear is dispensed with, and instead of a weight with one or two kilogrammes falling about thirty centimetres, a weight of 25 to 50 grammes falls a distance of one metre. The good results of this model are said to be due, in large measure, to the directness of its action and the avoidance of dissipation of energy in gear work. Experiments made with instruments of this type gave satisfactory results. The probable error for a single determination was found to be 0·03 second, but Mr. Wade believes that this will be reduced in the perfected instrument.

TURBULENCE ON A LARGE SCALE.—To say that a gas has viscosity, is a device to compensate in the bulk for the motions which are ignored in detail. Thus if the ignored motions are those within only a cubic tenth of a millimetre the viscosity, for air, is roughly 0·0002 cm.$^{-1}$ grm. sec.$^{-1}$. If, however, we ignore the gusts in a wind, then we must attribute to the smoothed wind a much greater viscosity, ranging, in the same unit, from 1 to 100. In this way the increase and veer of the mean wind in the first kilometre above ground have been explained by Åkerblom, Taylor, Hesselberg, Sverdrup, Schmidt, etc. Recently Albert Defant of Innsbruck has gone a stage further by asking what the viscosity must be if we ignore even the cyclones and anticyclones, so that we are left with a smooth general circulation of the atmosphere proceeding along the paths commonly shown in maps of the globe. A review of Defant's first paper on this subject appeared in NATURE of April 15 last, p. 469. In a second paper, "Die Bestimmung der Turbulenzgrössen der atmosphärischen Zirkulation aussertropischer Breiten" (Wien, *Akad. Wiss.*, 1921), he re-examines, by other methods, the viscosity to be attributed to this general circulation, and finds, as before, values round about 10^8 cm.$^{-1}$ grm. sec.$^{-1}$, that is to say, a billion times as great as that arising by ignoring molecular agitation only. This large value, 10^8, applies to friction across vertical planes, but apparently the friction across horizontal surfaces is an affair of gusts, not of cyclones. When the viscosity is known the conductivity for heat and for water vapour can be found by the theories of G. I. Taylor and W. Schmidt. The methods whereby Defant obtains this viscosity include a computation of "eddy-stresses" in accordance with Osborne Reynolds' theory from the hourly values of the wind at various heights. The direct eddy-stresses are in some cases as big as 0·3 millibar. Defant also makes a determination by way of the scattering of air to north and south of the mean-current after a passage of 3 days, using a formula due to L. F. Richardson.

A Florentine School of Physics and Optics.

By Dr L. C. Martin.

THE city of Florence, deservedly famous as a place of pilgrimage for lovers of art, is no less worthy of a visit on the part of students of science. The famous Museo di Fisica, with its Tribuna di Galilei and its collection of priceless instruments, will always attract the lion's share of attention, but a visit to the charming southern suburb of Arcetri, with the astronomical observatory and the newly erected Institute of Physics and Optics, will amply repay the time spent in making it.

On driving out from the city by the cypress avenue of the Villa Poggio Imperiale, the observatory is seen to the left crowning a lofty hill, on the side of which the red roofs of the Institute can be seen among the green of the surrounding gardens and vineyards. A wide view over the peaceful countryside is obtained on reaching the terrace.

The building is of the square form with centre courtyard usual in Italy, and is only two stories high. A cloister surrounds the courtyard on the ground level, and above the cloister a wide closed corridor affords interconnexion between the rooms on the upper floor. It is commonly held that a similar form of building is not suitable for the British Isles on account of the colder climate, but it may be doubted whether this view is correct; the arrangement has in the present case certainly proved most successful from many points of view. The rooms and corridors are light and airy, while the building is extremely compact and its low height makes for stability. There is little or no trouble from vibration, all machinery being housed in one side of the square at the back of the building. Lastly, and not least, a way has been found to combine beauty with utility, and it was not thought wasteful even in these modern times to follow the charming traditions of Florence by planting a garden to surround the well in the courtyard. This is shown in Fig. 1.

Fig. 1.—The Courtyard of the Physical Institute at Arcetri, Florence.

The Institute was erected immediately after the war to serve for post-graduate and research work in physics and optics. The physical laboratories are under the direction of Prof. A. Garbasso, who, during the last year, has served as Mayor of Florence. The optical laboratory is directed by Prof. A. Occhialini, the well-known editor of the *Revista d' Ottica*. In the coming year it is proposed to build an annexe devoted entirely to technical optics. Up to the present the teaching activity has been restricted to the physical side, but courses on optical subjects are being arranged and research and testing are already in progress. Accommodation is provided for thirty to forty students taking post-graduate courses in physics. The present students are drawn largely from the University of Pisa.

In the course of a short visit it is scarcely possible to notice all the features deserving attention. The arrangement of lecture theatre, class rooms, and research rooms is generally excellent, and it is evident that the needs of experimental work have been considered during design; for example, in one corner of the building it is possible to obtain the equivalent of a vertical circular shaft by removing the coverings of holes in the roof and floors, an arrangement which is of the greatest value in optical testing.

The usual wiring and switchboard for the distribution of electric current is provided, and there is also a separate high-tension circuit. Another point which seems admirable is the construction of the roomy apparatus cupboards in which three sides are of glass; they stand in the corridor on the first floor and exhibit the apparatus to advantage, a matter of importance in a teaching institution.

In the matter of equipment the usual lines have been generously followed. For example, the optical apparatus includes 30 and 20 plate echelons with appropriate spectroscopes, a Fabry and Perot interferometer, and a Nutting spectrophotometer, all by A. Hilger, Ltd. There is also a large spectrometer (with four reading microscopes for the circle) by the Société Genevoise. Other branches of physics seem to be supplied in a corresponding manner. Those who know something of the present cost of equipment of this kind will appreciate the intensity and vigour of the effort which Italy is making in the founding of this Institute.

In Florence as in few other cities one loses that sense of the remoteness of the past which oppresses the mind in more modern surroundings, and the splendour of bygone days seems still our own for guidance and inspiration. Such thoughts find a fitting expression in two frescoes which are seen on leaving the Institute by the main staircase. On the one side is seen Youth in the quietness and cool of the evening drinking of the fountain of ancient wisdom, while opposite we see Humanity in the glory of morning sunlight pressing upwards with eagerness and hope towards the hilltops.

I am indebted to Profs. Occhialini and Garbasso for photographs and information for the purposes of this article.

Fruit-Growing and Research.

THE application of scientific methods and principles is steadily gaining ground in fruit culture as in other branches of agriculture, and the numerous publications on the subject provide evidence of a widening interest in the matter, both as regards the scientific and the practical worker.

The earlier work of Spencer Pickering and the Duke of Bedford stimulated interest in the root systems of fruit trees, and at Long Ashton [1] the matter of root development under various conditions is being followed up. It appears that the method of treatment at the time of planting has little effect on the type of root produced, a new root system being derived from the collar region of the tree and little growth occurring elsewhere; aeration is considered to be a dominant factor in determining the actual point of origin of the new roots. Root formation and growth are most active at the beginning and towards the end of the season, the greatest increase in root length occurring during the latter period, at the time when shoot growth is rapidly decreasing. Other experiments deal with the extension of the root system throughout the soil, a matter which has a direct bearing on the degree of overlapping of roots when too close planting is practised.

On the pathological side special attention has been directed to leaf-scorch on fruit trees, and the trouble has been found to be due to various causative agents. Among the chief of these are unfavourable soil conditions, due to deficient food or water supply or to defective aeration owing to the mechanical character of the soil. Scorching is also attributed to the direct action of wind, to excessive heat falling on the leaf, or to injury to the vascular system of the plant, such as may be caused by ringing or by the presence of a fungus which penetrates the vascular tissue and interferes with the water supply to the leaves.

The importance of spraying to combat disease is now widely recognised, and at East Malling [2] direct experimental work is being carried out with fungicides on apple trees. Every fungicide tested reduces apple scab (*Venturia inæqualis*), though the degree of effectiveness varies, Bordeaux mixture usually proving the best. Generally speaking, the crop and the size of the fruit are improved by spraying, with certain exceptions, and there are indications that summer spraying may improve the keeping quality of the fruit by reducing attacks of brown-rot (*Sclerotinia fructigens*). An interesting point is that the effects of spraying are cumulative, sprayed trees being less heavily affected in the succeeding years.

A critical examination of the stocks used for stone fruits [3] shows that little or no attempt has hitherto been made to group them as has been done for those used for apples and pears, rapidity of growth and general availability being usually the deciding factors in the selection of stocks in any particular instance. The descriptions worked out at East Malling are the beginnings of an attempt to set up a permanent standard of classification and identification with the view of the ultimate improvement of stone fruit cultivation.

In an interesting survey on progress in methods of practical fruit-growing in the Journal of the Royal Agricultural Society of England,[4] the whole business, from the selection of a holding to the final packing of the fruit, is traced. Laying out and planting the fruit farm, raising and selecting trees, pruning, manuring, diseases, and pests are all brought under consideration in a way that provides suggestive reading for all interested in the subject, and its value is enhanced by a useful bibliography. In this connexion also attention may be directed to the collected leaflets [5] on fruit recently reissued by the Ministry of Agriculture, in which various problems the practical fruit-grower encounters in his work receive detailed consideration.

Volcanic Activity in Nigeria.

IN NATURE of July 15, p. 97, an account was given of volcanic activity in Nigeria during March–May last. The following extracts, from the reports of Mr. H. S. Cameron, acting Supervisor of Plantations in Nigeria, furnish some later information. They are placed at our disposal through the courtesy of the Colonial Office:—

On June 17 the manager of Bibundi informed me by telephone that lava streams had commenced to flow again, also that heavy damage was being done by floods. On June 18 I went to Bibundi, and going by trolley to Dollmanshohe I found the roadway of the bridge entirely swept away by floods and also one of the four piers gone. I went up the river, and after about a mile reached the first flow of lava, which had been advancing the day before but had now cooled and was stationary. Crossing from there to Wernerfelde, progress was shortly prevented by advancing lava; the stream here was molten, but its advance, which was more "creeping" than "flowing," was over a very wide area and on a gentle slope, and it seemed probable that eventually it would cool and turn the main lava stream down the old course of the Njonge river and extend into the sea, as part of the flow was then doing.

The flooding damage was considerable and I think unpreventable; the amount of water is so great that it is impossible to direct it. More than fifty inches of rain fell in the first seventeen days of June, and the water from an area which formerly fed three rivers and part of a fourth has now no channel: not only is an exit lacking, but rain falling on lava does not sink in and percolate through but rushes at once to the lowest level, so free drainage is more necessary than ever.

On June 22 I received a letter stating that the lava had broken through near Dollmanshohe bungalow, followed the course of the stream, and was threatening the hospital, which had been abandoned. On reaching the bridge-end at Dollmanshohe on June 25, I found that the whole of that division above the iron road had been covered with lava, and cascades of molten lava were flowing down the banks of the ravine. It was really a wonderful sight. The river bed was full of detached flows of lava fed from the Dollmanshohe plateau, where it had been massing during the past week. I inspected the whole length from near the Thormahlenfelde bungalow to the director's house, finding flowing lava everywhere. By afternoon the ravine was filled, and by 11 P.M. the lava had crossed the rail where the Government road turns

off and was advancing down the latter and towards it from various points along the river course on the left.

Owing to the steady progress between June 18 and 25, and the rapid flow on the latter date, I considered it advisable to order the removal of all the machinery and the salving so far as possible of all building materials worth removing from machine house, cacao house, hospital, and director's house.

On July 11 I again visited Bibundi. The lava had advanced considerably since June 25, but its activity is gradually dying out, though the lava streams from the crater, so far as can be seen in this very misty weather, continue as strong as ever. Probably there will be another period of rest and banking up to be followed by a further advance, and everything points to this following the line of the iron road and Government road to the cacao store and machine house, and possibly breaking through the main portion of Thormählenfelde to the Nmonne River higher up.

On July 15 the manager of Bibundi reported: "The main lava stream is quiet; but for the last three nights I have seen a large new stream coming down the mountain. It is very bright and much closer to this side than before."

The Royal Photographic Society's Exhibition.

THE Annual Exhibition of the Royal Photographic Society at 35 Russell Square remains open until October 28. Admission is free The natural history section of the scientific and technical division has improved considerably in recent years. There are still a good many single photographs of an animal, a flower, or an insect that have no particular interest, or if they have it is not indicated; but there are many series showing progressive changes, such as Dr. S. Hastings's nine illustrations of soil formation in the Alps, in which he shows the bare rock covered at first with crustaceous lichens, and traces the stages of vegetation until an alpine meadow is produced. Other series show many varieties of the same kind of thing, as Mr. C. H. Caffyn's thirty sections of calcareous, arenaceous, and igneous rocks, and Dr. Rodman's animal and vegetable hairs. With scarcely any exception the photography in this section is excellent.

Among the "Technical Applications of Photography" Dr. J. S Plaskett shows four photographs taken at the focus of the 72-inch reflecting telescope at the Dominion Astrophysical Observatory, Victoria, B C., which also give evidence of the accuracy of figure of the mirror. The Mount Wilson Observatory, Carnegie Institution of Washington, contributes specimens of the work of the 100-inch Hooker reflector and of the 60-inch reflector, as well as photographs of the unusual spectra of seven stars, made with these instruments. Enlarged negative prints of a latitude variation plate and a wave-length plate are among the exhibits of the Astronomer Royal, Greenwich.

The production of accurate comparative scales by photographic means is fully described and illustrated by Mr. A. E. Bawtree, and Mr. Wilfred Mark Webb shows how, by chemical and photographic means, a Russian internal passport was made to yield deleted details which showed that the document had done duty on four separate occasions for as many different persons.

Mr. G. A. Clarke illustrates upper cloud formations which support the theory of Prof. Bjerknes that depressions have their origin in the meeting of a warm, moist, equatorial current and a cold, dry, polar current. Cloud formation and structure is shown from the upper side by Mr. F. W. Baker.

There are many exhibits that deal with the technicalities of gelatine plate manufacture and the statistical properties of plates by workers in America, as well as in this country. We may refer specially to the beautiful photomicrographs of silver bromide crystals, at 3000 diameters, by Mr. A. P. H. Trivelli, and the characteristic curves of modern high-speed dry plates with photomicrographs of the grains that constitute the sensitive material by Mr. J. W. Grundy. Mr. Grundy also contributes a fine series of photographs taken under various conditions from a height of about 14,000 feet.

Among numerous radiographs by several workers the effect of the Potter-Bucky diaphragm is shown by Mr. R. B. Wilsey. This diaphragm consists of a grid made of parallel strips of lead foil, the planes of which are in line with the direction of the radiation from the tube. It is placed between the patient and the film, and moved during the exposure so that it may not show on the radiograph; it absorbs a large proportion of the scattered rays.

There is a large collection of colour transparencies, and among them some of scientific interest, but the most remarkable are the stereoscopic slides made on autochrome plates by Mr. S. Pegler. The successful reproduction of the colour and the brilliancy of silver plate, various articles of jewellery, and coloured stones, together with the realistic appearance, demonstrates possibilities of this method that are little known. C. J.

University and Educational Intelligence.

LONDON.—The senate of the university includes sixteen members elected by registered members of convocation and sixteen by the faculties Of the former, six are elected by the registered graduates in science; and of the latter, the faculty of science appoints four. There are two vacant seats in science, and five candidates have presented themselves as candidates for them. The candidates are: Dr. George Senter, principal of Birkbeck College, and author of a number of papers and other works on chemistry (Dr. Senter is a member of the faculty of science, and is therefore eligible for election as a representative of the faculty in the senate); Mr. T. Ll. Humberstone, an old student and associate of the Royal College of Science, well known to be particularly familiar with the work of the University and educational problems generally; Dr. Jessie White, who is especially interested in methods of teaching science; Dr. J. S. Bridges, director of education, Willesden; and Mr. C. W. Crook, headmaster, Central Secondary School, Wood Green. The poll closes on Tuesday next, Oct. 10, and it is hoped that graduates will not fail to send in their voting papers before that date.

ST. ANDREWS.—The honorary degree of LL.D. was conferred upon the Prince of Wales on September 28 In an address to his Royal Highness after the presentation, Dr. J. C. Irvine, principal of the university reminded him that St. Andrews was not only a place of beauty and the home of a noble game, but also a centre from which great movements had sprung and powerful influences had spread far and wide. The ancient university was ever ready to enlarge its activities, blending the wisdom of the past with the spirit of progress.

Calendar of Industrial Pioneers.

October 8, 1862. James Walker died.—An eminent civil engineer, Walker constructed many works of the greatest magnitude, and as engineer to the board of the Trinity House built the Bishop's Rock Lighthouse and the Smalls Lighthouse. In 1834 he succeeded Telford as president of the Institution of Civil Engineers, and held that position for eleven years.

October 9, 1902. George Wightwick Rendel died.—Born in 1833, Rendel was the second son of James Meadows Rendel. Trained under his father, he gained experience in bridge building in India, and in 1858 became a partner with Armstrong at Elswick, where, with Andrew Noble, he directed the ordnance works for twenty-four years. He was intimately associated with the development of the hydraulic system of gun mountings—the first mounting being fitted in H.M.S. *Thunderer* in 1877—and he was also a pioneer in the application of forced draught to warships. From 1882 to 1885 he was a civil lord of the Admiralty.

October 10, 1854. John Augustus Lloyd died.—At an early age Lloyd left England for South America, where he became an officer in the army of Bolivar. In 1827 he made a survey of the Isthmus of Panama. From 1831 to 1849 he was colonial engineer and surveyer of Mauritius, where he constructed many roads and bridges, a patent slip for ships, a breakwater, and the colonial observatory Among his writings was a paper read to the Institution of Civil Engineers on "Facilities for a Slip Canal between the Atlantic and Pacific." He died in the Crimea while on a Government Commission.

October 11, 1705. Guillaume Amontons died.—Employed for many years on public works in France, Amontons was a member of the Paris Academy of Sciences, and was known for his improvements in barometers and other instruments. In 1684 he suggested a means of signalling long distances by a type of semaphore telegraph

October 12, 1859. Robert Stephenson died.—The only son of George Stephenson, whom he assisted in the construction of the Liverpool and Manchester Railway, which was opened in 1830, Robert Stephenson became engineer to many of the early railways. Among his most famous works were the High Level Bridge at Newcastle, the Tubular Bridge over the Menai Straits, and the Victoria Bridge at Montreal He was elected a fellow of the Royal Society in 1849, and during 1856–57 served as president of the Institution of Civil Engineers. He was buried beside Telford in the nave of Westminster Abbey.

October 13, 1902. Peter Brotherhood died.—After studying at King's College, London, Brotherhood worked as a mechanical engineer at Swindon and at Maudslay's, Lambeth; in 1867 he set up in business for himself in London. In 1872 he introduced the three-cylinder engine adopted extensively for torpedoes, and in 1875 built the first steam engine coupled direct to a dynamo—this being fitted in the French battleship *Richelieu*. He also made many improvements in air-compressing machinery.

October 14, 1906. Sir Richard Tangye died.—One of the five brothers who built up one of the most important engineering works in Birmingham, Tangye and his brothers migrated to that city from Redruth. Setting up as tool and machine makers, they made a reputation by the construction of the hydraulic jacks by means of which Brunel launched the *Great Eastern*, and they afterwards became known all over the world as the makers of steam engines and pumping machinery.

Societies and Academies.

SWANSEA

Institute of Metals, September 21.—**J. E. Clennell**: Experiments on the oxide method of determining aluminium (Report to the Aluminium Corrosion Research Sub-Committee of the Corrosion Research Committee of the Institute) It was desired to find a direct method of determining aluminium in presence of iron and other impurities. Precipitating aluminium as hydroxide by alkali thiosulphates was fairly satisfactory, but the weight of precipitate generally exceeded the theoretical amount calculated from the aluminium known to be present. This excess was traced to small quantities of absorbed substances, notably salts of iron and sulphates, probably of aluminium A better method is as follows: Pass sulphur dioxide through the slightly ammoniacal solution, precipitating in dilute, faintly acid, boiling solution with sodium thiosulphate with addition of dilute acetic acid, washing by decantation with hot 1 per cent ammonium chloride, filtering and washing with hot water. Iron, zinc, manganese, and magnesium in ordinary amounts do not interfere, but when the first two are present in large quantity a double precipitation is necessary.—**Marie L. V. Gayler**: The constitution and age-hardening of alloys of aluminium with copper, magnesium, and silicon in the solid state. *Constitution.*—These alloys have been regarded as a ternary system since magnesium and silicon are added in the proportions of the compound magnesium silicide, which is very stable at all temperatures Microscopic examination shows that the solubility of copper is reduced from 4·5 per cent to 2 per cent. at 500° C. by the presence of 0·7 per cent magnesium silicide; while 2 per cent of copper reduces the solubility of magnesium silicide from 1·2 per cent. to 0·7 per cent. at 500° C At 250° C both constituents are turned out of solution when only 0·5 per cent. of each are present. *Age-Hardening.*—Brinell hardness measurements were made on alloys in which the percentage content of one constituent only was varied; they were quenched from 500° C. and allowed to age-harden at room temperature. Age-hardening is due to the difference in solubility at high and low temperatures of both copper and magnesium silicide, and the solubility in aluminium of both in the presence of each other. Heat treatment of age-hardened alloys caused a preliminary softening before an increase in hardness; this is probably due to the process by which both compounds tend to come out of solution. Derived differential curves of alloys which had been quenched, but not aged, show three critical points, the lowest is at a constant temperature, the temperature of the two upper critical points is lowered with increasing copper content, the intensity of the uppermost varies with the copper content. Probably this point is due to the precipitation of the copper compound and the second to the precipitation of magnesium silicide.—**D. Stockdale**: The copper-rich aluminium-copper alloys. Alloys of copper with aluminium up to 20 per cent. of aluminium have been investigated. Thermal data from the cooling-curves and from quenching experiments in conjunction with microscopic examination were used to obtain equilibrium diagrams. The minimum in the liquidus curve at 1031° C. with 8·3 per cent. of aluminium is a true eutectic point; a small arrest point at 1017° with alloys containing between 16·5 and 18 per cent. of aluminium has been discovered. Copper at 1000° C. can hold only 7·4 per cent. of aluminium in solid solution; at 500° C. and at lower temperatures, 9·8 per cent., although to obtain such an alloy a

long annealing is required. — R. **Seligman** and **P. Williams**: Cleaning aluminium utensils. Aluminium is not attacked by water-glass solutions or by hot soda solution containing a little sodium silicate. Attack by a 5 per cent soda solution is immediately arrested by the addition of an amount of sodium silicate equal to 1/100 of the soda. Satisfactory detergents consisting of a mixture of soda and sodium silicate are articles of commerce, among them are "Carbosil," "Pearl Dust," and "Aquamol."—W **Rosenhain** and J D **Grogan**: The effects of overheating and melting on aluminium. Exposure to an unduly high temperature during melting, and repeated re-melting even at ordinary melting temperatures, are thought to cause deterioration approximating to the condition generally described as "burnt" aluminium. High-grade aluminium was poured at temperatures up to 1000° C and also at the usual pouring temperature after heating for some hours at 1000° C. The castings rolled and tested in the annealed state showed no deterioration. High-grade aluminium and also aluminium containing ½ per cent each of iron and silicon were cast to ½-in slabs and rolled to 0·01 in sheet, the sheet was re-melted and the process repeated ten times. Test pieces from each melt showed no systematic change.

SYDNEY

Linnean Society of New South Wales, July 26.—Mr G A Waterhouse, president, in the chair.—A. E **Shaw**: Description of new Australasian Blattidae, with a note on the blattid coxa. Nine cockroaches are described as new, three belonging to Platyzosteria, five to Cutilia, and one doubtfully to Zonioploca.—H H **Karny**: A remarkable new gall-thrips from Australia. These thrips infest the branchlets of the "Belah" (*Casuarina Cambagei*) and cause rounded galls of aborted tissue to form, in which large colonies of thrips develop.—G F. **Hill**: A new Australian termite. The new species of Calotermes from near Condon, W A, is distinct from any described Australian species and easily distinguished in the soldier caste by the long narrow head, large mandibles, dentition, third joint of antennæ, and enlarged femora.—E W **Ferguson** and G. F **Hill**: Notes on Australian Tabanidæ, part ii. Eight new species, including 1 species of Silvius and 7 of Tabanus, and two varieties of species of Tabanus are described.—J **McLuckie**: Studies in symbiosis, part ii. The apogeotropic roots of *Macrozamia spiralis* and their physiological significance. Root-tubercles occur upon many of the seedlings and older plants of *Macrozamia spiralis*, particularly about the soil-level. They are seldom present on the more deeply situated secondary roots, but may be induced to develop by artificial inoculation. The root-tubercles are due to infection by soil bacteria, the presence of which stimulates the development of the cortex and sheath, so that the tubercles are more massive than ordinary roots.

Landowners and the State.

LORD BLEDISLOE, as president of the Agricultural Section of the British Association at Hull this year, struck a new note in his address. Put very briefly, his text was a demand for more leadership, and in particular for educated leadership by landowners in the business of farming. British farming has for the last two centuries in the main been carried on by tenants possessed of considerable capital, which is employed in the business and not in the land itself nor in its permanent equipment. The result, at any rate until fifty years ago, was successful. Complicated as the question of tenure was in detail, by custom it worked well on the whole; a sufficiency of capital was attracted to the land to permit of cultivation on a comparatively large scale with sufficient continuity to encourage experiment and improvement, until British farming, whether as regards operations of cultivation, productivity of crops grown or quality of stock bred, stood easily foremost in the whole world.

British agriculture no longer enjoys the same undisputed position. We can still point with pride to its technical excellence, but it has not succeeded in so adapting itself to the changed economic conditions as to continue to be regarded as a prosperous industry or to attract the confidence of capitalists. Farmers, despite some protestations, can still make a living out of it, because they can always adjust their style of farming to any range of prices, but the position of the other two parties to the occupation of the land is far from satisfactory. Landowners' rents do not represent a reasonable rate of interest on the money that has been expended on the buildings, etc. necessary to the working of the farm. A piece of average English land in prairie condition could not to-day be equipped as a farm and then let at a rent which would pay market interest on the capital expended in equipping it, even though no charge were made for the land itself. Landowners who sold their farms during the last few years were able after reinvestment to double and treble the income they had derived from them, and at the same time to relieve themselves of many of the calls upon the landlord's purse. Agricultural labourers, again, though they effected some improvement in their position during the war, are still the worst paid industrial class of any magnitude in the community. In the villages it is well recognised that a boy is likely to be better off if he can get on the railway, into the police, or any of the other occupations more or less available, rather than go upon the land.

The tenant-farming system, for all its advantages, appears to be breaking down, and Lord Bledisloe regards the landowners of the last generation or two

as in part responsible. From an abstract point of view the ordinary English tenant farm of 200 to 500 acres is no longer the economic unit it once was. At its inception it represented wholesale large scale production as compared with the generality of European farming, and as such it provided the food needed for the early industrial development of the country.

But with the enormous extension of wheat growing and meat production in the newer countries, the effect of which upon our markets began to become so apparent from the 'seventies of last century onwards, and with modern organisation of the import trade in food products from countries with a low wage standard, the English farmer no longer controls prices, and when he stands alone, he is selling as a retailer in a market dominated by much larger interests. It has become a terribly difficult market because Great Britain is now the one absolutely free emporium to which the surplus food products from every other food-producing country in the world are directed. With one or two minor exceptions (Denmark and Belgium are practically free-trade countries, but they are normally food exporters rather than buyers), the British farmer is met by a tariff wall whenever he has a surplus to export or a speciality to develop, and these difficulties are, at the moment, accentuated by the break in the Continental exchanges, which diverts to Britain even the limited quantities of food-stuffs the foreign industrialist had begun to purchase.

Some of these difficulties may be overcome by cooperation, never an easy matter to organise in a conservative community such as our farmers form, bred as they have been in an individualist organisation of business and imbued with the characteristic British tradition of standing alone. In any case, co-operation may be only a palliative; the economic flaw in the tenant-farming system probably is that the unit of management is too small. There is not work for a master in controlling the five to ten men employed on the ordinary English farm; as a managing head one man should be able to supervise the working of 1000 to 2000 acres, according to the class of land. Economic pressure would thus appear to be tending to move away from the present type of British farm in two directions, either towards the single-man holding, uneconomic as an instrument of production but in which compensation is found in the extra labour the occupier will give in exchange for his independence, or on the other hand, towards the really large farm which can take advantage of machinery and organisation.

Lord Bledisloe's main contention is that the landowner must either take the latter option and become the instructed business head of his estate treated as a single farm, or if he prefers not to take over the actual management, he must at least be the leader and *entrepreneur* of the associated businesses of his tenants. Not only is the holding of land a bad investment, but in a modern State the mere rent receiver will eventually be eliminated. Landlords must give service or perish as such, and Lord Bledisloe appeals to a class which has a long and honourable tradition behind it of service to the State to return to the land and so render a necessary service to a State that is becoming overweighted on the industrial side. He points out the two directions in which the landowner can lead his tenants and benefit both his estate and the course of agriculture. In the first place, the farmer to-day is not getting his fair share of the prices the consumer pays for food. While all the producing interests connected with the land are unprosperous and are being forced to contract their activities, the trading organisations which deal in the produce of land are paying handsome dividends and individual middlemen are growing rich. The consumer reviles the farmer because of the scarcity of food; the farmer knows he must restrict his production in order to make it pay at present prices, while the slightest production above the normal demand cuts away not merely profits but often cash returns, as may be seen over plums and potatoes at the moment. The distributing trade has entrenched itself in order to retain its war scale of margin, and the building famine in the country hinders the growth of competition. Lord Bledisloe gives a series of tables to show the discrepancy between retail and farmers' prices and the increase of that discrepancy since the war; in most cases the distributing trades take more than half the price the public pays. Coarse 'middlings' cost more than wheat, and readers of the *Times* a few days ago may have noticed that on the same day the price of London flour was put up while wheat was, in another column, reported as cheaper.

It is to this state of things Lord Bledisloe recommends landowners to turn their attention; can they not organise the businesses of their farmers into something capable of keeping the middlemen in check? They should be able to see further than the farmer, who has to look after his own business of production. Co-operation has made but little headway among farmers themselves; would it not be in a very different position if it had been whole-heartedly and intelligently backed by the landowners? Here is one opening for intelligence and leadership on the part of owners of land.

The other great opening is in connexion with education and research. The old race of landlords numbered among them great improvers of farming, such as Weston, Townshend, Coke, and Lawes. Even the much-abused farming covenants represented, to begin

with, better systems imposed upon their tenants by landlords. To-day, if English farming practice is in many respects still ahead of its competitors, it has become, comparatively speaking, not so alive to the applications of science. Farmers themselves are not quite what they were; the great industrial development of the last sixty years has been drawing away the brains from the more slowly moving pursuit of agriculture, and, speaking broadly, the present race of farmers are not educated up to their needs or their opportunities.

Here again the landowners have not been, but can be, leaders; they can become intelligence centres, they can stimulate the education of their tenants and of their tenants' sons, they can even insist on education in selecting their tenants. It is the lack of appreciation of science among landowners that has made it a plant of slow growth among their tenants.

The address is really a powerfully worded appeal from Lord Bledisloe to the landowning class to treat landowning as a vocation and to educate themselves for it. It is a far-sighted call for service, and coming from one who has so notably put into practice what he preaches, carries with it an authority which no ordinary admonition to progress can possess.

Bergson and Einstein.

Durée et Simultanéité: À propos de la théorie d'Einstein. Par Henri Bergson. Pp. viii + 245. (Paris: Félix Alcan, 1922.) 8 francs net.

EINSTEIN in his theory of relativity may be said to have thrown down a challenge in the scientific world of the same kind as that which Bergson in his theory of duration has thrown down in the philosophic world. Both theories are primarily concerned with a certain fundamental character in the experience of time. Both recognise a difference of nature, that is, a qualitative difference, between the time which enters into our equations of measurement and the time which is lived. At one point, however, Bergson seems to come into direct conflict with the Minkowski-Einstein scheme of a space-time continuum. This is in his conception of creative evolution. Creation means that the reality of the physical universe is of the nature of life or consciousness, a conception which implies the continued existence of the past in the present, and a universal moving forward into an open future. How is this consistent with the view that there is not one single universal time but as many different times as there are systems, and that there is no absolute simultaneity between events which take place at any two points if they are separate from one another in space?

Bergson has evidently been of opinion that for his own sake he must clear up his position on this crucial point. To do so has been no slight undertaking, for he has not been content to accept the principle of relativity from the physicists or to assume that its mathematics is correct. He has, therefore, deferred the resumption of his own philosophical work, interrupted by the war, and has set himself to study at first hand the mathematical equations of Lorentz and Einstein. It may interest readers of NATURE to know that Bergson specialised in mathematics in his student days to the extent of hesitating between it and philosophy when he had to choose a profession. The argument in his new work deals almost exclusively with the restricted theory, for it is that which affects directly the question of the reality of time. The relevance of the generalised theory is only touched upon. It is the subject of a "Final Remark," in which the nature of its importance for philosophy is indicated, but general relativity does not seem to Bergson to challenge, as the restricted relativity does, his theory that time as a universal flux or change is an intuited reality, while successive states are a spatialised time due to the intellectual mode of apprehending it.

Descartes in the Principles (ii 29) declares that in movement there is complete reciprocity; either of two objects changing their relative position may be considered as having moved or as having remained at rest. To this Sir Henry More replied (March 5, 1649): "When I am sitting still, and someone moving away a mile from me is red with fatigue, it is he who moves and I who am still." Nothing science can affirm concerning the relativity of perceived movement, measured by foot-rules and clocks, can disturb the inward feeling we have that we ourselves can effect movements and that the efforts we put forth in doing so are under our control. Here we have, then, in the most striking manner, the contrast between the intuitive mode and the intellectual mode of apprehending reality. Is there anything in the principle of relativity which conflicts with the conception of reality as fundamentally a duration which is intuited or lived? *Prima facie*, yes. The denial of absolute simultaneity seems completely inconsistent with it. This comes out most clearly in Einstein's paradox. "Suppose a traveller to be enclosed in a cannon-ball and projected from the earth with a velocity amounting to a twenty-thousandth of the velocity of light; suppose him to meet a star and be returned to earth; he will find when he leaves the cannon-ball that if he has been absent two years, the world in his absence has aged two hundred years." Any one who applies the mathematics of relativity and makes the simple calculation for the two systems, earth and cannon-ball, will find that the conclusion

follows with the same logical necessity as in Zeno's paradox that Achilles cannot overtake the tortoise.

There is, however, a limitation even for the relativist which, although it falls short of establishing an absolute, is important to keep in mind. There is no system of reference which a traveller can choose, by entering which he might depart and return to find the world younger, so that his journey would have been backward in time The reason is not the inconceivability of such a system, but the fact that it would bring us into conflict with the law of causality. The reversibility of causality which would require the effect to come into existence before the cause, is unthinkable. Such then is the paradox. Relativity requires that as we pass into a new system of reference the relative movement of the new system shall be compensated by changes in the spatio-temporal axes of co-ordination in order to keep constant the velocity of light. This means in the case supposed that two years of the one system is the equivalent of two hundred of the other.

Bergson's solution of Einstein's paradox follows the same line as his solution of the paradoxes of Zeno, but the special application of his principle has a particular interest. In the case of Zeno the essential point was the insistence on the continuity, in the meaning of absolute indivisibility, of true duration, the duration which is lived and intuited, as distinct from the infinitely divisible continuity, mathematically defined, of the schematised trajectory of the movement. The mathematical time which we measure is really space. In the case of Einstein's paradox Bergson argues that the two systems, which are discordant as to their simultaneity when taken as integral systems, must be considered as continuously related, and this is possible only so long as we do not abstract from the observer who is attached to each If, he says, we consider the two observers in their different systems to be continuously in communication it is clear that each, while regarding the other as a physicist co-ordinating a system, will regard that co-ordinated system from the standpoint of his own, and therefore, however different the system may be, in so far as the two observers are physicists and in so far as they are related observers, the duration intuited is one and the same for both. But here we shall ask, if the explanation is so simple, how does the paradox arise? Quite naturally, Bergson replies, and this is the striking part of his argument, because what the philosopher can do the physicist cannot. The philosopher's concern is with reality perceived or perceptible; he, therefore, can never lose sight of the interchangeability of the two systems. He keeps them together by a kind of continual coming and going between them. The physicist, on the other hand, whose only business is to co-ordinate the system as a whole, must choose one and stand by his choice. He cannot relate all the events of the universe to two systems of different axes of co-ordination at one and the same time. He must therefore regard the whole system as concordant or discordant with the whole of the other system, each taken as one and integral. For the physicist is not concerned with time intuited but only with time as a measurable dimension.

We may see, then, how Einstein is able to affirm that there are multiple times. We can place an imaginary physicist at every point of space and his time-system will necessarily be different from every other time-system; and our own time-system, so far as we are physicists, has no privilege over the imaginary time-systems. But, Bergson replies, into whichever of these imaginary time-systems we project ourselves, it becomes thereby time lived or intuited, and as we can conceive ourselves to pass into any of them, there is a real duration to which all the imaginary time-systems belong. Thus is restored to us the unique time, one and universal.

Such is Bergson's solution. Does it dispose of the problem? The argument is certainly calculated to reassure those who have been disturbed by the principle of relativity, and to comfort those who are made unhappy, rather than stimulated to activity, by paradox. Yet there are many indications in his book that Bergson himself does not feel he has said or is now saying the last word. In the final remark, to which we have already referred, he regards the generalised theory as an extension of the argument of the restricted theory with the difference that the emphasis is on space rather than on time. He suggests that the treatment of space on the same lines as those on which he has dealt with time would show that the multiple geometries are imaginary physicists' geometries abstracted from their relation to and transformability into the one and universal space-system which is the intuition of the living individual.

To a certain extent he is undoubtedly right, for we may say truly that the restricted relativity is a case in point of the generalised relativity. But there is a problem which Bergson has left untouched while giving indications that he is aware of it. This is the relativity of magnitudes. Even Einstein has not, so far, dealt with it specifically Weyl, in his endeavour to make the generalised theory include the whole realm of electro-magnetic phenomena, has foreshadowed a relativity even more fundamental and more universal than Einstein's, although so far he has found no means, such as Einstein found, of submitting the principle to experimental tests. In philosophy it is of the deepest significance. Not only is there no

absolute criterion of magnitude, but systems of reference are not even relatively in relations of magnitude to one another. It is only for the observer in a system of reference that there is a relation of magnitude within the system and that the system itself has relations of magnitude to other systems. Into whatever system an observer passes he carries into it his own constant norm of magnitude and he does not have to submit to the dimensions which the new system imposes on him. It is this aspect of the principle of relativity which has seemed to the present writer to require a philosophical principle like that of the Leibnizian monad to give it full expression. It is not enough to return to the mathematical principle of Descartes's mechanism. Mathematics and physics alike rest ultimately on the experience of active subjects, and this is why experimental tests are relevant. The monadic conception derives new meaning from the theory of reality as psychical duration, the concept which Bergson has made a new possession of human thought.

H. WILDON CARR.

The Molecular Scattering of Light.

Molecular Diffraction of Light. By Prof. C. V. Raman. Pp. x+103. (Calcutta: University of Calcutta, 1922.)

READERS of NATURE are already familiar with the important work which Prof. C. V. Raman has been carrying out in connexion with the scattering of light by small particles, for many of his results have been announced in these columns. In a small volume published by the University of Calcutta he has reviewed the present position of the subject of molecular diffraction of light, and has discussed the theory in a comprehensive survey which includes the case of gases, vapours, liquids, crystals, and amorphous solids.

Lord Rayleigh was the first to indicate the principles on which the problem may be handled, and he obtained a relation between the scattering power of the molecules of a gas, their number per unit volume, and the refractivity of the medium. As the energy scattered must be derived from the primary beam, the intensity of the latter must suffer an attenuation as it passes through the medium, and an expression can be derived for the attenuation coefficient. Prof. Raman discusses some criticisms of the theory and concludes that the principle of random phase which is assumed in the argument is justified, provided there exists the random distribution of the molecules which is required by Boyle's law. The ultimate justification of the principle rests on the complete non-uniformity in the spatial distribution of the molecules in so far as very small volume elements are concerned.

The first successful attempt to observe the scattering of light by dust-free air in the laboratory was made by Cabannes in 1915. Experimental work of great interest has been carried out by Prof. R. J. Strutt (the present Lord Rayleigh), who obtained the remarkable result that, in many gases, the scattered light is only partially polarised. This may be explained as due to the lack of symmetry of the molecules, and may furnish valuable information with regard to molecular configuration.

To the late Lord Rayleigh we owe the brilliant suggestion that the scattering of light by the molecules of air accounted in large measure both for the blue light of the sky and the observed degree of transparency of the atmosphere. Recent observations, principally at the Observatory on Mount Wilson, have confirmed the theory and have furnished a value for Avogadro's constant which is practically identical with that deduced from Millikan's measurements of the electronic charge. Prof. Raman has made observations on the polarisation of skylight on Mount Dodabetta (8750 feet above sea level) in the Nilgiris. As is well known, dust and haze are largely confined to the lower levels of the atmosphere. The influence of secondary scattering may be reduced very considerably by using a deep red filter, and allowance can be made for the effect of earthshine. The weaker component of polarisation was found to have 13 per cent. of the intensity of the stronger component. Only 4 per cent., however, was ascribable to molecular anisotropy, a result in good agreement with the latest laboratory measurements.

The principle of random phase on which Rayleigh's theory depends is not applicable in the case of highly condensed media such as dense vapours, liquids, and solids. In liquids, we may apply the theory developed by Einstein and Smoluchowski, in which scattering is considered not as due to individual particles but to small local variations of density arising from the heat movements of the molecules. A formula is obtained showing how the scattering power of a fluid is related to its refractivity. It is worthy of notice that the scattering power is proportional to the absolute temperature and to the compressibility of the liquid. When corrected for the effect of molecular anisotropy, the formula gives results in fair agreement with observations in non-fluorescent liquids, and it reduces automatically to the Rayleigh formula in the case of gaseous media. But, surprisingly enough, the law seems to break down in the case of gases under high pressure. Prof. Raman makes the interesting suggestion that this failure may mean that the continuous wave theory of light does not strictly represent the facts, and that we may perhaps find here experimental support for Einstein's conception that light itself consists of quantum units.

Q I

states explicitly of what these contents consist. This issue is, of course, in anticipation of the annual volume, which gives a complete record of the Association's proceedings at the particular meeting, but which cannot, in the nature of things, make its appearance until some time after its conclusion.

This practice of the Association, which is of comparatively recent origin, is altogether to be commended, and as a business proposition is to the credit of the management. Experience has shown that it meets a public demand. Members who attend a meeting are ready to purchase, at the comparatively low price of issue, a collected edition of the addresses, as are those who are unable to be present. The fact is significant of the increasing appreciation in which these addresses are held by the public. In the early days of the Association it was not considered obligatory on the part of a president of a section to prepare a special address by way of opening its proceedings, and he occasionally contented himself with a few general remarks before calling upon a member charged with the preparation of a report on the progress of the particular department of science with which the section concerned itself, either to read the report or to give an abstract of its contents. Failing the report he would call upon a member to present the first communication on the list, and in some such manner the business of the section would be begun. Gradually the present custom has been evolved, and the presidential addresses have become a valuable and most important feature of the work of the section—some people, indeed, would say the most valuable and important.

The presidents of sections nowadays are invariably representative men or women—recognised authorities on the special subjects with which the section deals. They are usually active workers in the development of knowledge on these subjects—persons with experience of research and of matured judgment, with a message of advice, counsel, or warning to communicate, or they may even promulgate a wholly new departure in scientific thought. Hence the eagerness and expectancy with which these utterances are awaited, not only by the professional members of the section but also by such portion of the general public as shows its interest in the progress of science either by attending the meetings of the Association, or following its proceedings in the press. The appreciation in which these sectional addresses are now held is further shown by the measures which the executive have been required to take in deference to public demand. Formerly the addresses were all given on the same day, and as a rule at the same hour, and they initiated the work of their respective sections. Nowadays special arrangements are made, so that members may have an opportunity of hearing as many as possible during the week over which the meeting extends. Their publication in collected form during the week of the meeting will be of service to those who for various reasons are unable to take advantage of such opportunity, and will be welcomed by others who may wish to study them in detail and at leisure. There are, of course, some, and they are particularly common among those of the student habit, upon whom the printed word makes a more effective impression than that spoken.

It is unnecessary on the present occasion to say anything at length concerning the contents of the volume before us. Any detailed examination or criticism is the more uncalled for, as most of the addresses themselves, slightly abridged in some cases, have been, or are being, reproduced in these columns. It is sufficient to say that the 1922 book worthily sustains the reputation which British Association addresses now enjoy, as well-written, scholarly productions, pregnant with thought, replete with fact and suggestion, stimulating and full of interest and inspiration to the contemplative kind. In an age which is pre-eminently scientific these books deserve the widest possible circulation, and in the interests of knowledge it is to be hoped that they will attain it.

Our Bookshelf.

Der fossile Mensch. Grundzüge einer Paläanthropologie. Von Prof. Dr. E. Werth. Erster Teil. Pp. iv+336. (Berlin: Gebrüder Borntraeger, 1921.) 20s.

ENGLISH students who wish to know what their German colleagues think of recent discoveries of fossil man will be somewhat disappointed when they consult this work. Its author, Prof. Werth, who has published several books on the Ice-age and allied geological subjects, has either never heard of the fossil remains discovered at Piltdown and fully described by Dr. Smith Woodward, or refuses to believe in their authenticity; at least no mention is made of them. Nor is any allusion made to the remains found at Boskop, South Africa, the fossil skull found at Talgai, Queensland, nor those found by Prof. Eugene Dubois at Wadjak, Java. On the other hand, full and welcome accounts are given of two important finds made in Germany during war-time. One of these was made at Ehringsdorf, near Weimar, where two fossil lower jaws were found. These are attributed—and rightly so—to Neanderthal man, whose distribution is thus carried beyond the watershed of the Rhine. The other discovery, which was made at Obercassel, near Bonn, has revealed the remains of a man and of a woman belonging to the last phase of the Ice-age, and regarded by their discoverers as members of the so-called Cromagnon race. The skull of the man serves very well as the prototype of many a specimen found in neolithic graves in Scandinavia and Britain, but has such outstanding cheek-bones, zygomatic arches and angles of the jaw (or jowls) as have never been seen in

European skulls hitherto. The width of the face in front of the ears is 153 mm., at the angles of the lower jaw 127 mm., betokening an extraordinary development of the masseter muscles. Notwithstanding these features, the skull is that of a strong, handsome, and big-headed man.

The opening chapters of this work are devoted to an orthodox and clearly worded description of Europe in the Ice-age. In dealing with human remains, Prof. Werth depends very largely on the methods and conclusions of Schwalbe and of Klaatsch. Prof. Werth accepts Schwalbe's verdict that Neanderthal man was not the precursor of modern man, but was extinguished by the arrival of the Aurignacian race in Europe. He is inclined to think the Cromagnon type represents a later invader of Europe, and accepts this type as the precursor of the long-headed modern Europeans– both of the dark Mediterranean and of the fair Scandinavian type. The work, of which this is Part 1, is well illustrated.

Studien an Infusorien uber Flimmerbewegung, Lokomotion und Reizbeantwortung. Von Dr. Friedrich Alverdes. (Arbeiten aus dem Gebeit der experimentellen Biologie, Heft 3) Pp. iv + 130. (Berlin: Gebruder Borntraeger, 1922.) 12s.

The little book under notice is a record of careful work, chiefly upon the behaviour of *Paramœcium caudatum*, although the three other species of Paramœcium, *Stentor polymorphus*, and other Infusoria, figure in some of the experiments. The author has made an especially detailed study of the movements of Paramœcium and of the action of its cilia, and his observations on its morphology are not without interest. He discusses the behaviour of these organisms when operated upon, and also their reactions to narcotics and other chemical stimuli and to the galvanic current

While the author admits the merit of Jennings's work in this field of study, he is, nevertheless, frequently in conflict with this worker, both in his observations of behaviour and his interpretations of them; but it is not certain that he thoroughly grasps Jennings's views, and it is noteworthy that the latest edition of "The Behaviour of the Lower Organisms" (Columbia Univ. Press, 1915) is not in Dr. Alverdes's Bibliography. Dr. Alverdes ranges himself energetically against all those who see in the Infusoria nothing but "small automata," and vigorously opposes the mechanistic interpretation of their behaviour Like Jennings, he denies that the local action theory of tropisms can explain completely the behaviour of these organisms He would substitute for it another view to which his researches have led him, but it is impossible, in the short space at our disposal, adequately to present this view or to criticise it. Undoubtedly Dr Alverdes's work is careful, and is marked throughout by independence of mind. He insists, with admirable emphasis, that little progress can come from the study of the Protista in unusual media or in media which are artificially prepared upon physico-chemical principles alone. The same argument might be applied with profit to all other work on the Protista.

In spite of a rather difficult and discursive style, the book should not be neglected by those who are interested in the problems with which it deals.

An Introduction to Electrodynamics: From the Standpoint of the Electron Theory. By Prof. Leigh Page. Pp. vi + 134. (Boston and London: Ginn and Co., 1922.) 10s. net.

Hitherto the mathematical equations of electrodynamics have been based on the experimental conclusions of Coulomb, Ampère, and Faraday. Even books which discuss relativity go no further than showing that these equations are co-variant for the Lorentz-Einstein transformation. In Prof. Page's book, however, the equations are derived directly from the principle of relativity. The mathematician will appreciate this procedure as it is more logical, but we think that the average reader will find the older methods more convincing. The units chosen are those advocated by Heaviside and Lorentz The value of the charge at any point is equal to the number of tubes of force diverging from the point, all matter is assumed to be made up of positive and negative electrons; electromagnetic force is defined in terms of the electric intensity of lines of force, and gravitational attraction between two electrons is supposed to be negligibly small The electrons carrying a current are all of the same sign, and their masses are positive. Hence the "mass of the current" is greater than the sum of the masses of the individual electrons composing it.

The author's methods of calculating the radiation from electrons are to be commended, and he also gives a good account of Laue's theory of the diffraction of X-rays The formulæ deduced for specific inductive capacity, magnetic permeability, and metallic conductivity agree fairly well with experimental results. The theories of Faraday's experiment showing the rotation of the plane of polarisation of light by a magnetic field and of the Zeeman effect are given briefly, but in a convincing way. We can commend this book to the electrician who has an advanced knowledge of mathematics and is interested in the latest theories

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof Dr. E. Abderhalden Lieferung 55. Abt. V *Methoden zum Studium der Funktionen der einzelnen Organe des tierischen Organismus* Teil 6, Heft 3 *Sinnesorgane: Lichtsinn und Auge.* Pp. 365-462. (Berlin und Wien Urban und Schwarzenberg, 1922.) 117 marks

This portion of the work, Abderhalden's "Handbuch," is the direct continuation of parts 3 and 4, which dealt with the biophysical methods used in investigating the living eye and its sensitivity to light. The first section, by Dr Vogt of Basel, is devoted to the method of examining the eye with light from which the red rays have been absorbed by passage through a concentrated solution of copper sulphate and a weak solution of erioviridine With such light, investigations of the yellow spot are rendered much easier and more accurate. The second section of 76 pages, by Dr Basler of Tubingen, deals with methods which in the main are intended to investigate the functions of the retina and its various parts. Sharpness of vision, irradiation, and detection of movement are some of the subjects dealt with. The concluding section, by Dr Samojloff of Breda, describes the photographic method he uses for studying the

movement of the eyeball from side to side. The treatment is in general more wordy than is desirable, but the work brings together in an accessible form a large amount of information hitherto buried in memoirs, published in most cases abroad.

Our Homeland Prehistoric Antiquities, and How to Study Them. By W. G. Clarke. (The Homeland Pocket Books, No. 13.) Pp. 139+plates. (London: The Homeland Association, Ltd., 37-38 Maiden Lane, 1922.) 4s. 6d. net.

MR. CLARKE'S little handbook on the prehistoric antiquities of Britain covers the whole subject from Eoliths to the Iron Age. One of its main objects, however, is to help the novice to discriminate between stones shaped by natural forces and those chipped by man. In so far as this is possible by means of the printed word, Mr. Clarke is a good guide, while his practical hints on where and how to look for implements will be of great assistance to those taking up field work for the first time. As it covers so wide a field the treatment is necessarily summary, while in dealing with controversial points conclusions are stated dogmatically, which, in a more ambitious work, would require extended discussion. For this reason, Mr. Clarke must be forgiven some over-hasty statements. The amount of information which he has succeeded in condensing into so small a compass is remarkable. There are few subjects connected with prehistoric peoples of these islands, whether it be their implements, their dwellings, or their modes of life, about which the beginner will not find sufficient information here to open a path to further study, and this, in a book of this type, is in itself a great achievement.

Homo (Os Modernos Estudos sobre a Origem do Homem.) By Prof. A. A. Mendes Corrêa. Pp. 318. (Lisboa; Porto; Coimbra: Lumen Empresa Internacional Editora, 1921.) n.p.

IN this country the work of Portuguese anthropologists is not too widely known; yet it is deserving of more attention than it receives. In prehistoric archæology and somatology, investigations are being carried on which, if not considerable in bulk, are of some importance for students of European ethnology. We therefore welcome the opportunity of directing attention to this book by Prof. Mendes Corrêa, in which the most recent discoveries and hypotheses relating to the origin and descent of man are critically discussed. Each chapter deals with some one aspect of the problem, beginning with "the animal origin of man," and passing on to "evolution," the evidence of palæontology, *Pithecanthropus erectus*, the skeletal remains of prehistoric man, anthropogenesis, and a detailed exposition of the neo-monogenistic point of view. It is interesting to note that the author, in the case of the Trinil and Piltdown remains, adheres to the view in the former that the fragment of skull is simian and the femur human, and in the latter that the cranium is human and the jaw simian. A final chapter summarises the author's views, published elsewhere, on the influence of environment in the formation of races, and reviews the problems which await elucidation by further discoveries.

Sound: An Elementary Text-book for Schools and Colleges. By Dr. J. W. Capstick. (Cambridge Physical Series.) Second edition. Pp. viii+393. (Cambridge: At the University Press, 1922.) 7s. 6d.

IN the second edition of Dr. Capstick's text-book of sound, a chapter has been added giving an outline of some of the more important applications of acoustics to military operations during the war of 1914–18. The author is not very successful in conveying in the fewest possible words a clear idea of the apparatus employed, and his descriptions would have been improved by the use of diagrams. It must, however, be pointed out that some of the diagrams in the earlier chapters are by no means perfect. In Fig. 95 the pendulum would quickly damage the mercury cup, and it is doubtful whether the Bell telephone in Fig. 99 would have been recognised by its inventor. The granular transmitter, inadequately illustrated on page 222, does not serve in this primitive form as a suitable microphone for use in a hydrophone. The author has obviously made a slip when he says that in signalling under water the sound is received by a submerged microphone similar to a *receiving* telephone. In spite of some defects the volume will serve a useful purpose as a class-book for schools.

Sewerage and Sewage Disposal: A Textbook. By L. Metcalf and H. P. Eddy. Pp. xiv+598. (New York and London: McGraw-Hill Book Co., Inc., 1922.) 25s. net.

THE volume before us is the work of the authors of a three-volume treatise on "American Sewerage Practice," and is the result of a demand for a shorter book suitable for students who have not a great deal of time to devote to this subject. The early sections of the book deal with the main outlines of the problem of sewerage—the quantity of sewage to be expected, storm water, hydraulics, etc. Methods of surveying and excavating are then treated, together with the details of carrying out the work. The later sections deal with the chemical and biological characteristics of sewage and with disposal methods. There is a chapter on cost-estimating at the end of the volume. The authors are engineers whose practice brings them into intimate contact with the matters treated; this is reflected in their book, which cannot fail to be of service to students, British as well as American. The volume is profusely illustrated and is thoroughly up-to-date. There are some useful graphs, among which we note one giving the discharge of egg-shaped sewers running full depth, which is based on Kutter's formula.

Manuel de tournage du bois. Par Hippolyte Gaschet. (Bibliothèque Professionnelle.) Pp. 248. (Paris: J.-B. Baillière et Fils, 1922.) 10 francs net.

A VERY good account of the tools used and the methods employed in wood-turning is given in this little volume, which will be found to be supplementary, in some respects, to English works on the same subject. The language difficulty will probably prevent the book from reaching the hands of many young workers in this country, but manual instructors should find it useful, especially in view of the graduated series of exercises which is included at the end of the volume.

Periodicities.

THE recent paper by Sir William Beveridge on "Wheat Prices and Rainfall" (Journal of the Royal Statistical Society, vol. 85, pp. 412-478, 1922) raises a rather important question of principle which is involved not only in discussions over the existence of periodicities, but also over relationships between different variables.

Before Schuster's papers on the periodogram it was customary for a period to be accepted as real provided that it had an amplitude comparable with that of the original figures under analysis; and he revolutionised the treatment of the subject by showing that if the squares of the intensities of the various periodic terms are plotted in a periodogram, and if the data are those of an entirely chance distribution, then the average value of an ordinate being a, the probability that a particular ordinate will equal or exceed ka is e^{-k}. Sir William Beveridge is accordingly perfectly justified in taking Schuster's sunspot period of 11·125 years, or Brückner's 34·8 year period, and deciding that these periods probably occur in his wheat prices if the corresponding intensities are three or four times the average. But he, like many other investigators, goes a stage further, and after picking out the largest from a large number of intensities he applies the same criterion as if no selection had occurred. It is, however, clear that if we have a hundred intensities the average of which, a, is derived from a number of random figures, then the probable value of the largest of these chance intensities will not be a but will be considerably greater, and it is only when the largest amplitude actually derived materially exceeds the theoretical chance value thus obtained that reality can be inferred.

Taking the periodicities of wheat prices on pp 457-459 between 5 years and 40 years,[1] I estimate that the "width of a line" ranges from 0·1 year for a 5 years' period, through 0·5 at 12 years to 4 years at 33 years, and accordingly that the number of independent periods between 5 years and 40 is in this case about 51. The value of a, the average intensity, being 5·898, it is easily seen that the chance of all the 51 random intensities being less than $3a$ is $(1 - e^{-3})^{51}$, or 0·074, so that the chance of at least one intensity greater than $3a$ is 0·926, not e^{-3} or 0·050, as is habitually assumed. Instead of the chance of an occurrence of $3a$ "making a *prima facie* case for enquiry" (p 424), the odds are 12 to 1 in favour of its production by mere chance The chance of at least two intensities above $3a$ is 0·728, of three it is 0·470, of four 0·248, of five 0·109, of six 0·0403, of seven 0·0127, of nine 0·00085, and of eleven 0·00003

Thus it is not until six intensities over $3a$ are found that the chance of production by pure luck is less than 1 in 20 It is also easily found that if the chance of all the 51 intensities being less than na is to be 19/20, n is 6·9, *i.e.* the greatest intensity for wheat price fluctuations must be 41, not 18, before the probability of its being due to luck is reduced to 1/20; and if the likelihood is to be 1/100 we must have $n = 8·5$, the corresponding wheat-price intensity being 50. Of intensities greater than 41 Sir William Beveridge found four, and greater than 50 only two.

At first sight it might seem that the agreement between Sir William Beveridge's forecasted synthesis rainfall curve and the actual rainfall was too great to be explained by a few harmonic terms, but the correlation co-efficient of 0·38 (see p 475) indicates that while 0·38 of the rainfall variations are accounted for, only $(0·38)^2$, or about a seventh, of the independent factors which control these variations have been ascertained.

As pointed out in a paper "On the Criterion for the Reality of Relationships or Periodicities," in the Indian Meteorological Memoirs (vol 21, No. 9, 1914), the same principle is valid when discussing relationships. If we are examining the effect of rainfall on temperature and ascertain that the correlation co-efficient between the rainfall and temperature of the same month in a particular English county is four times the probable error, we may infer that the effect is highly probable But if we work out the co-efficients of that temperature with a hundred factors taken at random, *e.g* with the monthly rainfall of Tashkend 5·8 years previously, and pick out the largest co-efficient, it would be wrong to compare it with the average co-efficient produced by mere chance, as shown in the paper referred to, the probable value of the largest of 100 co-efficients is 4·01 times as great as the probable value of one taken at random GILBERT T. WALKER.

Meteorological Office, Simla, August 24

DR. WALKER's note contains, I think, a valid and valuable criticism of the procedure commonly adopted hitherto in comparing individual intensities with the average intensity in harmonic analysis. It would lead me now to modify in several ways my general discussion of the "test of intensity" (pp. 422-424 of my paper in the Journal of the Royal Statistical Society I was particularly careful, however, in that paper to avoid laying stress on intensity as such. The net result of Dr. Walker's calculations is not to weaken but to confirm my main thesis: that a number of real periodicities exist in European wheat prices from 1550 to 1850

According to these calculations, the chance of my getting by pure luck between five and forty years one intensity as great as $3a$ is 0·926, but the chance of my getting seven such intensities is 0·0127, and that of getting eleven is 0·00003 Actually I have, between five and forty years, fifteen intensities above $3a$ (= 17·69); the odds are therefore 80 to 1 that at least nine of these intensities, and 33,000 to 1 that at least five of them, are not due to luck. Obviously every such intensity does, in the circumstances, present a *prima facie* case for further inquiry, the object of the inquiry being to determine which of the 15 intensities have the strongest probabilities of being due to real periods.

In that inquiry the actual height of the intensity in any case (the "test of intensity") is only one and not necessarily the most important point for consideration. As Dr. Walker shows, an intensity in my periodogram of nearly seven times the average might well be due to pure luck (the odds being only 20 to 1 against it). On the other hand, a much lower intensity might represent a true and perfectly regular but weak periodicity, just as a quite small correlation co-efficient may prove a real though weak connexion, if the number of cases compared is very large. Indication of the same period in each half of a sequence when analysed separately (the "test of

[1] Sir William Beveridge points out on pp 423-424 that amplitudes for periods of less than 5 years are inevitably diminished, while those above 31 are diminished by the process employed for eliminating secular trend I calculate that the intensity at 35 years should be multiplied by $(0·87)^{-2}$ or 1·3, and that at 54 by 3·8.

continuity ") and in independent sequences (the "test of agreement with other records ") are often more important criteria of reality than is the height of the intensity itself. The former test, at least, should never be neglected; it has led me to relegate to my fourth class as merely "possible," several periods, such as those near 11, 17, and 24 years, indicated by high intensities in the whole sequence, but failing in either the first or the second half.

Ultimately, of my fifteen intensities between 5 and 40 years, I have treated only nine (at 5·100, 5·671, 5·960, 8·050, 9·750, 12·840, 15·225, 19·900, and 35·500 years respectively) as certainly or probably due to real periodicities, because they show in all cases perfect or fair continuity and in most an agreement with other records. The smallest of these fifteen intensities (21·72 at 7·417 years) in fact equals not $3a$ but $3·683a$. If with this revised figure, the probabilities are calculated in the way suggested by Dr. Walker, the odds that at least nine of the fifteen intensities are not due to luck work out at more than 2000 to 1, while the odds in favour of seven at least are 14,000 to 1.

This remarkable result, which seems to establish beyond all reasonable doubt the reign of periodicities in wheat prices, is not affected by the fact that of the fifteen intensities only four are so high that any one of the four, if it occurred alone and had to be judged by height alone, would have odds of more than 20 to 1 in its favour. Each intensity does not occur alone. Every period, moreover, to which I attach importance rests on more evidence than mere height in my periodogram.

With reference to the last paragraph but one of Dr. Walker's note, on the relation of my synthetic curve and the rainfall, I should like to emphasise the point made in my paper (pp. 449-450) that the synthetic curve as now drawn represents only a first approximation of the roughest possible character; the correlation co-efficient of 0·38 between it and the rainfall from 1850 to 1921 is sufficient to demonstrate some connexion between the wheat price cycles and the rainfall, but is in no sense to be treated as a measure of the degree of connexion. In constructing the synthetic curve, for instance, the periodicities have all been treated as of equal importance; inspection shows that weighting according to the intensities would almost certainly give a better fit and so a higher co-efficient of correlation. In many other ways a more accurate determination of the cycles is required. How high a correlation might ultimately be obtained as the result of this, it is impossible now to say, but it might easily prove to be very high indeed. Unfortunately, I have no resources for carrying my own investigations further for the present; I can only hope that others may be better placed. W. H. BEVERIDGE.

One Possible Cause for Atmospheric Electric Phenomena. A Query.

MAY I ask Sir Arthur Schuster or Dr. Chree or some other authority whether there is any serious objection to an idea like the following.

The sun being radio-active emits not only gamma rays, which ionise the atmosphere, but also alpha and beta particles. The alpha particles will be stopped by the upper layers of atmosphere, charging them positively, while the beta particles will be more penetrating, and might even reach the ground, charging it negatively; though I admit that thirty inches of mercury is a serious obstruction. But, as Arrhenius showed, the beta particles would be magnetically inveigled towards the poles, where they might descend with down currents: whereas the alpha particles—most numerous near the tropics—would be sustained by up currents; and thereafter the separated charges would reunite with familiar dielectric disruption. OLIVER LODGE.

Normanton, Lake, Salisbury, Sept. 29.

School Instruction in Botany.

IN the article on "School Instruction in Botany" in NATURE of September 2, p. 329, the report on the botany gardens of the James Allen's Girls' School, recently published by the Board of Education, was reviewed. As I am not only the author of the report but also the initiator and organiser of the botany gardens at Dulwich, I shall be glad if space can be afforded me to reply to the following comment at the end of the article: "No mention is made in the Report of the utilisation of the botany gardens for the observation of animal life." The omission is due to the fact that the report was written in 1915 (see prefatory note) when some of the "gardens," which are now of great help in studying animal life, were in an undeveloped condition.

For example, in 1915 the oak trees in the new wood were only from three to four years old and looked somewhat like sticks, as shown in Plate 10. Since 1915 the trees have grown so much that blackbirds, hedge sparrows, and a thrush have built nests, laid their eggs and in all cases but one reared their young in our wood. Advantage of this has been taken and many girls have visited the nests. During outdoor lessons, girls have learned to recognise birds which frequent the school garden, and have become familiar with their calls and songs.

In the spring term the awakening of the numerous frogs which hibernate in the school pond is eagerly awaited. For a short period the pond is densely populated by hundreds of croaking frogs. Later, the development of the tadpoles through all the stages is watched with the keenest interest by girls of all ages. Observation of animal life in the pond includes the study of the life-histories of china mark moths, dragon flies, newts, great water beetles, water boatmen, and water snails. On one occasion last term many girls watched the various stages in the emergence of a china mark moth from its chrysalis.

In these and in other ways the botany gardens at the James Allen's Girls' School are utilised for the observation of animal life. LILIAN J. CLARKE.

East Dulwich Grove, S.E. 22, September 28.

Transcription of Russian Names.

IN his further letter (NATURE, July 15, p. 78) Lord Gleichen refers to the Royal Geographical Society's System (II.) for the transcription of foreign alphabets into English. A copy of this system has just reached us and impresses us with its completeness and utility, especially for rendering place-names into English.

With regard to the transcription of Russian names we agree with Lord Gleichen that French, German, and hybrid transcriptions are unsatisfactory, but we would advocate, with Prof. Brauner, an international system, and for this purpose the Czech transcriptions have much to recommend them.

In the first place, the Serbian alphabet contains fewer letters than the Russian, and is thus inadequate to allow of accurate transcription from Russian by

the Serbo-Croatian rules. Czech transcription has the advantage of being complete.

The following examples may serve to make this clear. Russian а has only one sound, as in "master." It has the same sound in Czech, but the English *a* has several sounds. If ж is rendered by *j* it is liable to mispronunciation; if transcribed to the Czech ž this liability does not arise. Russian у is always pronounced like the Czech *u* (like *oo* in the English word "hook"). Russian х can be correctly rendered by the Czech *ch*.

"Hard mute" and "soft mute" (ъ and ь) can only be transcribed into Czech, using the hook ˇ after the consonant. Russian ы has no other European sound except the Czech *y*. The different pronunciation of the Russian е, ѣ, э cannot be easily expressed in English, but this becomes easy by using the Czech ě for the first two, especially the second.

It may be pointed out that the Czech transcription is already employed in the International Catalogue of Scientific Literature, and for some years German journals (*e.g. Zeitschr. f. anorg. Chem.*) have employed letters with diacritical marks in their transcription of Russian names (*e.g.* "Žemczuznyj," which in Czech is "Žemčužný").

The objection, urged by Lord Gleichen, to the use of diacritical marks exists, but is relatively small. Most scientific journals already have such type, which is indeed necessary if Czech names are to be printed correctly. Newspapers naturally lag behind such a journal as NATURE in matters of this kind, but in time these too will doubtless find it necessary to have letters with diacritical marks in their founts.

Lord Gleichen also asks how many English people can correctly pronounce Czech letters like č. It is regrettable, but nevertheless true, that the correct pronunciation of foreign words is not a great characteristic of the British people, but it is as easy to learn how to pronounce Czech words as it is those of other languages. The example which was chosen by Lord Gleichen is poor, because the sound "č" exactly corresponds to the English sound "ch" (*e.g.* "church").

Colour Vision and Syntony.

IN NATURE of September 9, p. 357, Prof. E. H. Barton has shown how a syntonic hypothesis of colour vision may be made to represent the trichromatic theory of colour vision. There are numerous facts which are quite inconsistent with any form of the trichromatic theory. These are given in detail in my recent book on the "Physiology of Vision" and subsequent papers, and no attempt has been made to answer any one of them. Every fact points to the visual purple being the visual substance which, sensitising the liquid surrounding the cones, sets up a visual impulse in the cones when decomposed by light. Houstoun's explanation of the physical processes is in complete accordance with the facts, and so far as I am aware no valid objection to it has been found.

Any theory of vision must explain the movement of the positive after-image in the retina. For example, if the positive after-image of a small white triangle on black velvet be obtained with one eye, on moving the head with a jerk, both eyes being covered, an irregular white figure will be seen some little distance away from the clearly cut black triangle, the negative after-image in the original position which is seen when a small amount of light is allowed to enter the eye through the lids. Another very simple method of seeing this movement of the positive after-image is to look at three windows on awaking, which are separated by walls; on closing and covering the eyes, well defined positive after-images of the windows separated by black spaces corresponding to the walls are seen. On covering the eyes and moving the head from side to side the after-images all blend into one, the black spaces being obliterated.

Let us compare the model given by Prof. Barton with the known facts of vision. For any particular light the three vibrators acting together should give the luminosity curve for that light. Barton has placed the red vibrator at about λ760 μμ, here the red has very little luminosity, whereas a driver of the length of the vibrator at this point will produce most effect. Again, drivers corresponding to the infra-red or ultra-violet will affect the red or violet vibrators respectively, whereas these regions are invisible.

When we come to colour blindness the trichromatic theory fails completely. How on this theory can the fact that more than fifty per cent of dangerously colour blind people can pass the wool test be explained? The fact that a dichromic may have a luminosity curve similar to the normal, that the trichromic have only three colour sensations and designate the yellow region as red-green, and the other degrees of colour and light perception, has to be explained.

The Green Ray at Sunset and Sunrise.

THE review by Sir Arthur Schuster of Mulder's book on the green ray or green flash at rising and setting of the sun, in NATURE of September 16, p. 370, leads me to make the following remarks.

There are, in reality, two distinct phenomena which go under the name of the green flash. The first, probably the one most usually seen and the only one to which the epithet properly applies, is certainly an after-image in an eye fatigued by the red light of the sun. I have seen it many times, only at sunset, and in many localities—on the Red Sea (twice in one evening owing to the sun being occluded by a narrow bank of cloud prior to its actual setting), in Devonshire, and even in London as the sun set behind University College Hospital.

This phenomenon can be reproduced quite easily in the laboratory by means of an artificial red sun, as I demonstrated a few years ago at a meeting of the Physical Society of London.

The second phenomenon, which I have never been successful in seeing and of which I can say little, is evidently due to atmospheric dispersion; and, from the published accounts, I should judge that it should be called the blue sun or multicoloured sun or spectrum flash. It would seem to be much more rare, as I gather from Sir Arthur Schuster's previously made descriptions that it requires rather special conditions.

If this subject should get into elementary text-books, as recommended, at least let the account of it be complete.

Photography of Bullets in Flight.

By PHILIP P. QUAYLE, Assistant Physicist, National Bureau of Standards, U.S.A.

INSTANTANEOUS photography by means of an electric spark provides the investigator of high-speed phenomena with a most valuable source of data. Such photographs are of the shadow variety, the bullet shadow being projected upon a photographic plate by a spark of great intensity and short duration. If the bullet is moving with a speed equal to or greater than that of sound, it propagates from both its nose and base a compressional wave. Light from the photographing spark in passing through the denser atmosphere of the compressional wave is refracted as by a lens, so that the wave front is also projected upon the photographic plate with the bullet. The method lends itself readily to the investigation of a projectile's stability at various points along its trajectory and to many allied problems of exterior ballistics. Instructive photographs of the recoil and shell ejection of automatic rifles, pistols, and machine guns may also be obtained in this manner.

FIG. 1.—Automatic pistol in position of extreme recoil, empty cartridge case not yet ejected. T, trigger; R, receiver; A, arm operating trigger.

Among the most important of the early contributions in this field of research are the admirable spark photographs by Prof. C. V. Boys (NATURE, Vol. 47, pp. 415 and 440) who greatly simplified the elaborate apparatus of Prof. E. Mach. In Prof. Boys's apparatus the bullet was employed to close the spark circuit, and this method has been followed in experiments which have been carried on since that time, so far as the present writer is aware.

In the method described in this article the setting-off or triggering of the electric spark by which the photographs are taken is controlled by the compressional wave produced by the flight of the bullet, so that no wires or other portions of the apparatus need appear on the plates. Since the sound wave is used to trigger the photographing spark, the position of the rifle firing the bullet may be varied at will without affecting the functioning of the apparatus, the only requirement being that the bullet shall have a speed greater than that of sound. When the speed of the bullet is less than that of sound the muzzle blast may be used to trigger the spark. In such cases the rifle must not be moved.

In Prof. Boys's type of apparatus the photographing spark is set off by the closing of a secondary gap by the bullet itself. In the present apparatus a much more powerful spark may be used than would otherwise be possible, because the potential available for the photographing spark is not limited by the dielectric strength of some trigger gap of fixed and small dimensions.

The regulation of the potential of the spark is essential, however, since great irregularities in time occur when the apparatus is not operated at the same potential, the spark occurring earlier or later than the transit of the bullet across the plate. This, of course, precludes satisfactory records when working with modern high-speed bullets. When the proper potential has been attained a signal light is automatically turned on.

No lens system is employed in the apparatus. An arrangement which has been found very satisfactory places all of the photographic apparatus, except the trigger, inside a small light-tight house.

The trigger itself is located outside the house and near the trajectory. This trigger is an interrupter of the type used by the French in connexion with the Joly chronograph. The use of this instrument and the type of springs used in the photographing-spark-switch were suggested by Dr. D. C. Miller, of the Case School of Applied Science, where the apparatus was developed. The trigger consists of a metal diaphragm about 2 inches in diameter enclosed in a circular metal box. The diaphragm forms one side of an air-tight enclosure, and on the inside face of the diaphragm is attached a circuit breaking mechanism. This circuit-breaker functions when the crack wave emanating from the bullet strikes the diaphragm, which in turn throws back a small hammer, thus interrupting the circuit and tripping the photographing-spark-switch, with which it is connected in series.

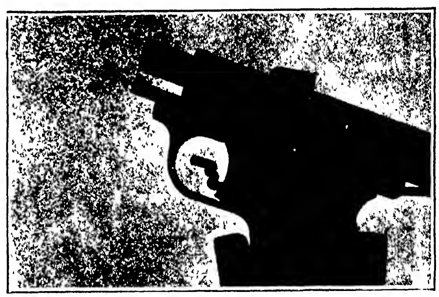

FIG. 2.—Automatic pistol, empty cartridge case just emerging from the receiver.

The essential parts of the photographic apparatus consist of a large Leyden jar battery charged by a static machine which is motor driven, the control switch for the motor being mounted on the table with the rifle. A potential regulator which is connected across the battery functions when the proper potential has been reached, and trips a switch which disconnects the battery from the charging machine and short-circuits the terminals of the latter. The switch when tripped turns on a signal light located outside the apparatus house as a signal to the rifle operator to fire.

When operating the apparatus the general sequence of events is as follows:

The photographing-spark-switch and battery-switch inside the apparatus house are set, the lights turned out, and the slide of the plateholder drawn. The operator then leaves the apparatus house by means of a light-tight passage and starts the static-machine motor by closing the table switch. He then makes any necessary

Fig. 3.—Automatic pistol, empty cartridge case ejected from receiver.

correction to the aiming and fires when the signal light appears. The bullet leaves the rifle and on its way to the apparatus house passes the trigger upon the diaphragm of which the sound wave impinges. This immediately trips the photographing-spark-switch and it starts to close the trigger gap in the spark circuit. The bullet continues on past the trigger, entering the apparatus house through a sheet of thin paper, used to shut out the light, and arrives in front of the photographic plate, upon which it is then projected by the photographing spark. The motor switch is then opened and the slide replaced in the plateholder, which may then be taken to the dark room and developed.

In case the speed of the bullets to be photographed is not known, a piece of paper or wire screen is placed in the path of the bullet in front of the photographic plate, and if a puncture in the screen is shown when the plate is developed, evidently the bullet had gone past the plate before the spark occurred. The trigger must then be moved back from the plate and the process repeated. Continuing in this manner the position of the bullet when the spark occurs will soon be bracketed within limits sufficiently small, so that an observer inside the apparatus house may see the bullet as the spark illuminates it. Visual adjustment only is then used until most of the bullets are seen in the desired locality when the spark occurs.

The apparatus is provided with two light gaps, one horizontal and the other vertical. This arrangement facilitates the taking of two photographs of the same bullet, a plan and elevation view. This is particularly useful in investigating a projectile of an unstable character having a tendency to tumble, since from the two views its actual position in space may be constructed.

The two coaxial waves which the bullet propagates from its nose and base appear on the photograph (Fig. 4) to have different slopes. This arises from the projection, for while the axis of the wave is parallel to the photographic plate, and therefore projected in proportion to its length, the radius of the projected wave is somewhat inclined to the plate and causes the distortion. The true angle of the conical sound wave in any may, however, be readily computed, from which the speed of the bullet producing the wave may be determined.[1]

In obtaining the photographs of the Colt automatic 25-calibre pistol, reproduced in Figs. 1, 2, and 3, the interrupter trigger was removed from the circuit and a timing device substituted, which consists of two electromagnets connected in series and adjustable in height, their function being to drop two steel balls at the same time when the key opening their circuit was depressed. One of these balls fell on a lever which pulled the trigger T of the automatic pistol by exerting tension on the arm A (see Fig. 1). The other ball, released from a greater height at the same time as the first, impinged on a device setting off the photographing spark. By this means any reasonable lag or lead in the firing of the pistol with respect to the occurrence of the photographing spark could be obtained. The firing apparatus is obviously not a precision instrument and could, of course, be replaced by an accurate timing device should the investigator require information of such a character.

The turbulent gases of the propelling charge are clearly shown in Figs. 1, 2, and 3. All these photographs of the automatic pistol represent a stage in the recoil relatively long after the ejection of the bullet from the muzzle, since it will be seen that the receiver R has reached the position of extreme recoil and the empty cartridge case is being ejected in Figs. 2 and 3.

Fig. 4.—30 Calibre boat-tailed bullet, approximate speed [illegible] feet per second.

If the height of the ball which triggers the spark is changed progressively by some small known amount, a series of photographs of such an automatic pistol at slightly different calculable time intervals could be secured. From the data obtainable from such photographs a pressure time curve could be computed.

The Study of Man.[1]

By H. J. E. PEAKE.

A CHANGE has been creeping over our science. Twelve years ago anthropologists were devoting their energies to the tracing out of the evolution of customs and material culture, assuming that, where similarities were found in different parts of the world, they were due to independent origins. It was assumed that the workings of the human mind were everywhere similar, and that, given similar conditions, similar customs would originate. The evolution of civilisation was looked upon as a single line of advance, conditioned by the unalterable nature of the human mind, and that barbarian and savage cultures were but forms of arrested development, and indicated very closely past stages of civilised communities.

But a fresh school of thought has come into prominence. According to this new view discoveries are made but once, and when resemblances are found between the cultures of different communities, even though widely separated, this is due to some connexion between them. According to the new school, the development of civilisation has been proceeding by many different paths, in response to as many types of environment, but these various advances have frequently met, and from the clash of two cultures has arisen another, often different, more complex, and usually more highly developed than either of its parents.

The old school looked upon the advance of culture as a single highway, along which different groups had been wandering at varying paces, so that, while some had traversed long distances, others had progressed but a short way. The new school, on the other hand, conceives of each group as traversing its own particular way, but that the paths frequently meet, cross, or coalesce, and that where the greatest number of paths have joined, there the pace has been quickest.

The older school, basing its views of the development of civilisation upon the doctrine of Evolution, has called itself the Evolutionary School. The newer, while believing no less in Evolution, feels it a duty to trace the various stages through which each type of civilisation has passed, rather than to assume that these stages have followed the succession observable elsewhere; thus, as historical factors form a large part of its inquiry, it has been termed the Historical School.[2]

The first note announcing the coming change was sounded from this chair eleven years ago,[3] and during the interval which has elapsed the new school has gained many adherents. All will not subscribe to the dictum that no discovery has been made twice; nevertheless there is a tendency not to assume an independent origin for any custom until it has been proved that such could not have been introduced from some other area.

These tendencies have led the anthropologist to inquire into the history of the peoples whose civilisation he is studying, and to note, too, minute points in their environment. At the same time geography began to take special note of man and his doings. This anthropogeography concerned itself with inquiring into the reactions between man and his environment, and though at first the environment was the main object of the geographer's attention, he is now inclined to pay more attention to its effect upon man. Thus anthropology and geography have been drawing closer, and as the latter is a recognised subject in our schools, no small amount of anthropological knowledge has been instilled into the minds of our boys and girls.

It might have been expected that the historians before the geographers would have been attracted to the anthropological approach, but recent events have up to now engrossed their attention. Signs have not been lacking, however, that the study of peoples and their customs, rather than of kings and politicians, is gaining ground, and we may look with confidence towards closer relations between the studies of history and anthropology.

Again, we may notice an increasing interest in our subject among sociologists and economists. These have focussed their attention upon the social organisation and economic well-being of civilised communities, with the view of presenting an orderly array of facts and principles before the political leaders. There has, however, been a tendency to trace these modern conditions back into the past, and to use for comparison examples drawn from the social organisation or economic conditions of communities living under simpler conditions. While these studies overlap those of the anthropologist, the methods used are different. We are working from the simple to the complex, they begin with highly developed conditions and thence work back to the primitive.

Lastly, we must not forget the students of the classical languages. In spite of many advantages which they possess at schools and universities, they have been losing in popularity, and the reason is not far to seek. So long as there were fresh works to be studied and imperfect texts to be emended, there was no lack of devotees to classical literature. Later, comparative philology gave fresh life to such studies, and certain views current among mid-nineteenth-century philologists gave also an impetus to the re-study of Greek mythology. But about 1890 such studies became unfashionable, and many classical scholars turned to anthropology with great advantage both to themselves and to us.

It is doubtless as a result of these converging movements that the general public is taking an interest in anthropological studies, and that works of a general nature, summing up the state of knowledge in its different branches, are in great request. The educated public wish to know more of the science of man, yet I fear they are too often perplexed by the discordant utterances of anthropologists, many of whom seem to be far from certain as to the message they have to deliver.

In their turn not a few anthropologists feel a like uncertainty as to the ultimate purpose of their studies, and are not clear as to how the results of their investigations can be of any benefit to humanity. These are points well worthy of consideration; for, as we were reminded from this chair two years ago,[4] anthropology, if it is to do its duty, must be useful to the State,

or to humanity in general. Even the scope of the science is by no means clear to all, and would be differently defined by various students. It may not be out of place, therefore, to consider in detail the scope and content of anthropology, then its aims and the services it may render to mankind.

To the outside world anthropology seems to consist of the study of flint implements, skeletons, and the ways of savage men, and to many students of the subject its boundaries are scarcely more extensive. Yet civilised people also are men, and anthropology should include these within its survey. That other scientific workers, historians, geographers, sociologists, and economists, study civilised man is no reason why the anthropologist should fail to take him into account, for his point of view differs in many respects from theirs. I would suggest, therefore, that all types of men, from the most civilised to the most primitive, in all times and in all places, come within the scope of anthropology.

Anthropology is the study of man, but we need a more accurate definition. A former occupant of this chair has declared that "anthropology is the whole history of man as fired by the idea of evolution. Man in evolution—that is the subject in its full reach." He adds: "Anthropology studies man as he occurs at all known times. It studies him as he occurs in all known parts of the world. It studies him body and soul together." [5]

Anthropology may, therefore, be defined as the study of the origin and evolution of man and his works. What, then, separates anthropology from the other studies which are concerned with man is, that the anthropologist studies him from all points of view—that his is a synthetic study; above all, that evolution is his watchword, that his study is, in fact, not static but dynamic.

If, then, we grant that anthropology is the synthetic study of the evolution of man and his manifold activities, we are dealing with a subject so vast that some subdivision becomes necessary if we are to realise what the study involves. Such divisions or classification must be arbitrary, but we may consider the subject as divided primarily into two main categories, "man" and "his works."

But man himself cannot be considered from one aspect only and it seems fitting that the anthropologist should consider that man consists of body and mind; the study of these is the special province of the anatomist, the physical anthropologist, and the psychologist. Here, again, it may be asserted that anatomy and psychology are distinct sciences, but anatomy, in so far as it helps us to understand the evolution of man, and again as it helps us to trace the variations in the human frame, is and always has been reckoned a branch of anthropology. Again, in the case of psychology, there is much which is not, strictly speaking, anthropological. On the other hand, in so far as psychology enables us to trace the development of the human mind from that of the animal, and in so far, too, as it can interpret the causes which have led to various forms of human activity, it is a branch of our science. If, too, it can help us to ascertain whether certain fundamental mental traits are normally associated with certain physical types, psychology will provide anthropologists with a means of interpreting many of the phenomena which they have noted but cannot fully explain.

[5] Marett, R. R. "Anthropology," p. 1.

The works of man are so varied that it is no easy task to classify them. We may, however, first distinguish the work of man's hands, his material culture, from his other activities. Under this heading we should include his tools, weapons, pottery, and textiles; his dwellings, tombs, and temples; his architecture and his art.

Next, we have the problems concerned with language, which we may consider as dealing with the means whereby men hold intercourse with one another. This heading might well include gesture at one end and writing at the other. Hitherto anthropologists have confined their attention too exclusively to the tongues of backward tribes, and left the speech of more advanced peoples to the philologists. I would plead, however, that language is such an essential element in human culture that comparative philologists might well consider themselves as anthropologists.

Lastly, we have social organisation and all that may be included under the terms "customs" and "institutions," a varied group, leading to the study of law and religion. Here, again, we come in contact with other studies—those of the lawyer, political economist, and theologian; but though the anthropologist is studying the same facts, his range is wider and his outlook more dynamic.

Thus it will be seen that in the three divisions of man's work, as well as in the two aspects of man himself, the anthropologist finds other workers in the field. But whereas these other sciences are concerned only with some part of man and his works, and are limited frequently to recent times and civilised communities, it is the province of the anthropologist to review them as a whole, in all times and in all places, and to trace their evolution from the simplest to the most complex.

If we accept the views of the historical school, anthropology becomes a new method of treating historical material. It is, in fact, the history of man and his civilisation, drawn not so much from written documents as from actual remains, whether of material objects or of customs and beliefs. It is concerned with wars only so far as these have produced a change in the population or language of a region. It is interested in kings only when these functionaries have retained customs indicative either of priesthood or divinity. It is interested less in legal enactments than in customary institutions, less in official theology than in the beliefs of the people; the acts of politicians concern it not so much as do the habits of humbler folk.

From some points of view anthropology may be considered as a department of zoology. A century ago zoologists were engaged in studying the higher animals, and for a time neglected the "radiate mob." Then all interest was focussed upon lowly forms, and the protozoa occupied a disproportionate part of their attention. Lately, again, their work has been more evenly distributed over the whole field. This choice of groups for special study was not due to mere caprice. The more obvious forms of life were first studied; then attention was focussed upon the simpler organisms; for, from the study of these, the zoologist was able to grasp

the underlying principles of life. These lessons learnt, he was able to attack the problems affecting the welfare of mankind.

So with the student of man. For many centuries historians, philosophers, and theologians have been studying the ways of civilised humanity, though not by the methods of the anthropologist. For, just as they were attracted by the higher groups of men, so were they fascinated by the more conspicuous individuals. During the nineteenth century, students were attracted towards the backward types of humanity, partly because of their very unlikeness to ourselves, and of recent years because they felt that the customs of these peoples were fast disappearing. But from a scientific point of view, the paramount reason was because it was felt that in such simple societies we should find the germ from which human civilisation had begun.

Much of the force of this last argument is disappearing as the evolutionary school gives place to the historical. We are becoming aware that the civilisation of backward peoples is more complex than was at first believed. We are giving up the belief that such people have preserved our ancestral types alive to the present day, for we are realising that they represent not so much our ancestors as our poor relations.

Though we must abandon the ancestral view, and cease to believe that these backward communities represent to-day the conditions under which we dwelt in the past, the institutions of these folk are in many respects less complex than our own, and it is possible to study them from every aspect with far greater ease than we could do in the case of one of the higher civilisations. Since it is the function of anthropology to study man synthetically, this is a great advantage. When dealing with these simpler problems we can evolve a method and a discipline to be applied in more complicated cases. Again, the backward peoples have no written history, and we are forced in this case to restore their past by other means. This has led to the development of fresh methods of attacking the problems of the past, which may prove of value in the case of more advanced communities.

For these reasons the study of backward peoples still has great value for the anthropologist. He has not yet solved all the problems concerned with the dawn of civilisation, nor has he yet perfected his methods and discipline. More workers and expert workers are needed in this field, and so it is that our universities devote the greater part of their energies to training students for this purpose. There are many students, however, who cannot visit wild lands to study the ways of their inhabitants. Some of these, it is true, may sift the material collected by their colleagues, though they will be at considerable disadvantage if they have had no personal experience of the people with which their material deals.

The time seems to have arrived when anthropologists should not concentrate so exclusively upon these lowly cultures, but might carry on their researches into those civilisations which have advanced further in their evolution. Not that I wish to deprecate in any way the study of backward peoples, or to discourage students from researches in that direction; but I would suggest that some anthropologists might initiate a closer inquiry into the conditions of more civilised peoples in addition to the studies already described.

We have in the Old World three great centres of culture, each of which has been in the van of progress, and each of which has contributed to the advance of the others. These are the civilisations of China, Hindustan, and what I will call the European Region.

Though our relations with China and Japan have been intimate for several generations, and many of our compatriots are familiar with both countries, it is surprising how little we know of either of these people from the anthropological point of view. This is the more to be regretted since for more than half a century Japan has been adopting features from Western civilisation, while there are signs that the same movement is beginning in China. So far those who have made themselves familiar with the languages of the Far East have studied the art, literature, philosophy, and religion of these regions, rather than those aspects which more properly belong to our subject.

What concerns us more nearly in this country is the Indian Region. Here we have a well-defined province, peopled by successive waves of different races, speaking different languages, and with different customs and beliefs: an apparently inextricable tangle of diverse elements in various stages of cultural evolution. A vast amount of material has been gathered in the past, though such collecting has not been proceeding so fast during the last generation; but basic problems are still unsolved, and seem at times well-nigh insoluble. Perhaps it is this superabundance of material, or it may be the apparent hopelessness of the task, which has diminished the interest taken in these studies during the past few years. This attitude is regrettable, and the only redeeming feature is the extremely active and intelligent interest in these problems now taken by various groups of Indian students, especially in the University of Calcutta.

I have suggested that perhaps the lack of interest in such matters among Anglo-Indians, and especially among members of the Indian Civil Service, may be due to the apparent hopelessness of reaching a solution of any of the problems involved. It may also be due to the fact that they are sent out from this country to govern a population with different cultures and beliefs, and traditions wholly unlike those of this continent, without having received in most cases any preparation which will enable them to study, appreciate, or understand an alien civilisation. Thus they misunderstand those among whom they are sent, and are in turn misunderstood. Guiltless of any evil intent, they offend the susceptibilities of those among whom their lot is cast, and acts are put down to indifference which are only the product of ignorance. After making their initial mistakes the more intelligent set to work to study the people committed to their charge, but faced with problems of extreme intricacy, and without any previous training, more often than not they give up the attempt as hopeless.

That candidates for the Indian Civil Service should receive a full training in anthropology before leaving this country has been pleaded time after time by this Section and by the Anthropological Institute, and though I repeat the plea, which will probably be as useless as its predecessors, I would add more. The problems con-

fronting the anthropologist and the administrator in India are of such extreme complexity that it needs a very considerable amount of combined action and research even to lay down the method and the lines along which future inquiries should be made. Such a school of thought, such a nucleus around which further research may be grouped, does not yet exist; the materials out of which it can be formed can scarcely yet be found. Yet until such a nucleus has been created, and has gathered around it a devoted band of researchers, no true understanding will be found of the problems which daily confront both peoples, and the East and the West will remain apart, subject to mutual recriminations, the natural outcome of mutual misunderstanding.

One solution only do I see to this dilemma. For many years past there have been institutions at Athens and Rome, where carefully chosen students have spent several years studying the ancient and modern conditions of those cities and their people. By this means a group of Englishmen have returned to this country well informed, not only as to the ancient but the modern conditions of Greece and Italy. Besides this we have had in each of the capitals of those two States an institution which has acted as a centre or focus of research into the civilisation of those countries. Although the main objects in both cases have been the true understanding of the cultures of the distant past, the constant intercourse of students of both nationalities working for a common end has resulted in a better understanding on the part of each of the aims and ideals of the other. I have no hesitation in saying that the existence of the British Schools at Athens and Rome has been of enormous value in bringing about and preserving friendly relations between the people of this country and those of Greece and Italy.

I cannot help feeling that a similar institution in India, served by a sympathetic and well-trained staff, to which carefully selected university men might go for a few years of post-graduate study, would go far towards removing many of the misunderstandings which are causing friction between the British and Indian peoples. Such a British School in India, if it is to be a success, should not be a Government institution, but should be founded and endowed by private benefactors of both nationalities. It would be a centre around which would gather all anthropological work in the peninsula, while it would enable the British students to arrive at a truer understanding of Indian ideals and help Indians to grasp more fully the relations subsisting between the Indian and European civilisations.

Lastly we come to the European Region, extending southward to the Sahara, and eastwards to Mesopotamia. Throughout this region the racial basis of the population is similar, though the proportion of the elements varies. Also throughout the region there has been, from the earliest days, free communication and no great barriers to trade and migration.

Until the last fifteen hundred years the civilisation of this area was fairly uniform, though its highest and earliest developments were in the south-east, while the northern zones lagged behind and were on the outer fringe. Nevertheless it formed from palæolithic times one cultural region, and this became more marked and homogeneous during the days of the Roman Empire. Two forces from without destroyed that mighty empire and divided the region into two halves; and as each of these forces adopted different religious views, the European cultural region became divided into two. We have, therefore, to treat the European cultural region as two, the civilisations of Islam and Christendom.

Though the separation of these two halves is relatively recent, their ideals have grown divergent, while the inhabitants of both zones are no nearer to a true understanding of one another. Political difficulties in the Near East are the natural result of such misunderstandings, and the remedy here is to achieve a truer appreciation of other points of view. A more thorough knowledge of the anthropological factors of the case seems to be a necessary preliminary to such mutual understanding, and since the League of Nations and the Versailles Treaty have seen fit to add to our responsibilities in this area, it is an urgent necessity that some of our anthropologists should pay closer attention to the problems of the Near East.

And now with regard to Christendom. Are we to consider that our duties as anthropologists end with alien cultures? Is Christendom so united that misunderstandings cannot arise within its borders? At the close of a great war we can scarcely claim that there is no room for our studies.

There has been a tendency hitherto to regard anthropology as a science dealing with backward peoples, and it has been felt that to apply its principles to neighbouring peoples might be looked upon as an insult. If, however, we agree that all mankind are fit material for the anthropologist's investigations, we need have no hesitation in studying their material culture, social organisation, and religious beliefs, just as already for practical purposes we study their languages. There is not a country in Europe in which we may not find features of an anthropological nature which separate its population from the inhabitants of other areas. It is these differences which come to the front when trouble is brewing, and these are the factors which we need to understand if we are to avoid giving offence in moments of national irritation. Constant travel by people alive to the importance of such inquiries will in time so influence the public opinion of many of the nations of Europe that misunderstandings will be less frequent, and national sensitiveness less prone to take offence at words and actions which are not intended to provoke.

But it is not only foreign countries and their inhabitants which the anthropologist needs to study. In every country there are different strata in the population which have different customs and a different outlook. The British Isles are no exception to this rule; history records the successive arrivals of Romans, Saxons, Danes, and Normans, and the study of prehistoric remains shows us that these invasions have been preceded by a greater number in earlier days. Just as the physical type of the Briton is far from uniform, so are his mental outlook and his ideals and beliefs. Quite apart from the differences observable in the different countries which compose our group of islands, we find also that the population insensibly divides itself into classes, differing but slightly except in name from what we know in India as castes. These classes in the British

Isles have had their origin in the successive waves of conquest which these islands have suffered. Individuals have freely passed from one class to another, but though the individuals have changed the classes have remained. Owing to the constant interchange in blood the physical characters of the different classes are much alike, as are their fundamental mental traits, but in material culture, language, social organisation, and to some extent religious beliefs, they differ widely. Here then again, in our own country, there is work for the anthropologist who never leaves these shores.

Turning now to the aims of anthropology and to the means whereby it may become of service to the State and to mankind in general, we see that it is of the utmost importance that those who are sent to govern or administer areas and districts mainly occupied by backward peoples should have received sufficient training in the science to enable them, in the shortest possible space of time, and consequently with the fewest possible initial mistakes, to govern a people whose customs, traditions, and beliefs are very different from their own, without offending the susceptibilities of their subjects.

We are an Imperial people, and during the last few centuries we have taken upon ourselves a lion's share of the white man's self-imposed burden, and the lives and well-being of millions of our backward brethren have been entrusted to our charge. Recent events have, by means of mandates, added largely to our responsibilities in this respect. We, of all nations, cannot disregard this fundamental duty of despatching our proconsuls fitted to undertake these great responsibilities.

But the burden we have undertaken extends not only to backward peoples; we have been called upon to govern or to advise the governments of peoples who have a civilisation little, if at all, inferior to our own, and to whom at one time we have been indebted for much of the culture that we now enjoy. The civilisations of these regions are infinitely more complex, and the people are not homogeneous, but are divided into numerous sections, differing in language, religion, and social customs. In these regions we meet with anthropological problems of infinite difficulty and complexity, on the solution of which depend the peace and well-being of the population. Yet our representatives go to take up their duties in these lands with little or no previous training, and it is only a marvel that errors of tact, due to ignorance, are not more common.

In these civilised regions race consciousness has been growing fast during the last half-century, and errors of tact and manners, which were submitted to in former times, though not with a good grace, are now actively resented, and the old methods of government are discredited. It may not yet be too late to remedy this evil, if no time is lost in giving a full anthropological training to those who are sent to administer these regions.

But we are not only an Imperial people, governing and administering regions with alien populations; we are also a wandering and adventurous people. The nomadic spirit of our ancestors is still alive within us; our ships, like those of the Vikings of old, are to be seen in every sea. So it comes that our people will be found in all lands and all climates from the Arctic circle to the Equator.

All these wandering Britons come in contact with the inhabitants of the lands they visit, creating various impressions, sometimes good, more often bad. Had they a fuller knowledge of the customs and opinions of the people they visit, or even a truer appreciation of the fact that diverse customs and opinions exist and should be respected, we should not have to record the creation of so many bad impressions. Luckily our people, as a rule, have much common sense, and often a desire to please, so this trouble is thus to some extent mitigated; but the difficulties that have arisen from ignorance of the ways of others, from too insular an outlook, in fact, from a lack of appreciation of the anthropological standpoint, are making us and our government heartily disliked in nearly every quarter of the globe. It is to remedy these difficulties, and the danger to the peace of the world which is threatened thereby, that I would advocate an increased study of anthropology by all sections of the community. Herein lies one of the chief means by which our science may become of service to mankind.

It is not my business to draft a scheme for the furtherance of anthropological studies. Two of our universities offer degrees in this subject, and others a diploma; courses of instruction on some sections of the subject are given there and elsewhere. Many teachers of geography are introducing much anthropological matter into their curricula, and there are signs that some historical teachers may follow suit, so that the subject-matter, if not the name, is not unknown in some of our schools. But we have much lost time to make up and the matter is urgent.

We cannot, of course, expect all our people to be trained anthropologists and to understand fully all the ways of the people they may chance to meet in their wanderings. What matters far more is that they should appreciate the fact that different peoples have had different pasts and so act differently in response to the same stimuli. Further, that all this diversity has its value; that we cannot be sure that one culture is in all respects superior to another, still less that ours is the best and the only one which is of consequence. It is not so much the facts that matter as the spirit of anthropology; we need not so much that our people should have anthropological knowledge as that they should learn to think anthropologically.

It is needless for me to remind you that the world is in a state of very unstable equilibrium—that the crust is, so to speak, cracked in many places, and that the fissures are becoming wider and deeper, and that fresh fissures are constantly appearing, not only in distant lands but nearer home. Again, this crust, if I may continue the geological metaphor, is stratified, and there are horizontal as well as vertical cleavages, which are daily becoming more marked. It is to the interest of humanity that these breaches should be healed and the cracks stopped, or we may find the civilisation of the world, which has grown up through long millennia at the cost of enormous struggles, break up into a thousand fragments. Such a break in the culture of the European Region followed the dissolution of the Roman Empire, and more than a thousand years were needed to heal it; nay, some of the cracks then made have never yet been closed.

Anything that may help to avert such a disaster is

important to the human race, and there is no greater danger at present than the alienation of the peoples of Asia and the Near East. Much of the ill-feeling engendered in India, Egypt, and elsewhere is the product of misunderstandings, due to a lack of appreciation on both sides of the opinions and views of the other party, and there seems to be no better method of removing such misunderstandings than a sympathetic study of one another's culture; to this end anthropology offers the most hopeful approach.

Obituary.

Dr. David Sharp, F.R.S.

Dr. David Sharp, whose name, it has been well said, is a household word wherever the science of entomology is pursued, died on August 27 at his home at Brockenhurst. His love of entomology, the great and continuing enthusiasm of his life, dated from his early childhood. Born in 1840 at Towcester, Northamptonshire, his early years were passed at Whittlebury, Northants, and at Stony Stratford. His parents later moved to London, and it was at Loudoun Road, St. John's Wood, that Herbert Spencer was an inmate of Sharp's father's house, as Spencer himself has related in his autobiography. Sharp himself said that his youthful intimacy with Spencer had influenced him considerably, and throughout his life he retained in Spencer's work an interest which found expression in the publication in 1904 of an article on "the place of Herbert Spencer in biology."

Sharp was destined by his father for a business career, but, finding this uncongenial, he studied medicine in London and afterwards at Edinburgh University, where he graduated in 1866 with the degrees M.B. and C.M. Specialising in the treatment of mental illnesses, he resided for some years at Thornhill in Dumfriesshire. He left Scotland in 1884 and lived at Shirley Warren, Southampton, and afterwards at Wilmington, near Dartford, Kent. Early in 1890 he was appointed curator of the insect collections of the University Museum of Zoology, Cambridge, a post which he resigned early in 1909 He then retired to Brockenhurst, where he passed the rest of his days.

Most of his multitudinous writings are systematic works on the Coleoptera, to which he devoted the greater part of his life, but many deal with other insects or with life-histories, or have a still wider bearing, for his learning extended to a wonderful degree over the whole field of entomology. He had an unrivalled knowledge of the British Coleoptera, and already in 1869 had published a monograph of nearly 200 pages on the obscure genus Homalota. His list of the Coleoptera of Scotland appeared in the early volumes of the *Scottish Naturalist*, and he published two catalogues of the Coleopterous fauna of Britain, the second in collaboration with Canon W. W. Fowler. His numerous other studies of British beetles form a series of papers continuing to the last years of his life

Sharp's biggest works on foreign Coleoptera are the monograph of water-beetles (Dytiscidae) published by the Royal Dublin Society in 1882, and his contributions to the "Biologia Centrali-Americana." In the latter he wrote the whole of the volume on Adephaga and Staphylinidae, more than 800 pages, the greater part of the volume on Clavicorns, and three other important sections. He also published in 1876 a paper of nearly 400 pages on the Staphylinidae of the Amazons. On New Zealand beetles, a fauna in which he was specially interested, he produced a long series of memoirs. One can barely allude to his papers on the beetles of Japan, an important series, and to others on those of Ceylon, Southern India, the White Nile, etc., with many more, far too numerous to mention Systematists, knowing the work required for the production of a single careful description, will appreciate the immense amount of toil needed to achieve these results Special mention must be made of Sharp's work on the faunas of islands. A series of earlier papers on Hawaiian beetles was but the prelude to his labours as secretary of the committee appointed in 1890 to investigate that fauna, and as editor of the three large volumes of the "Fauna Hawaiiensis," of which he himself wrote several considerable parts. He was moreover a member of the committee appointed in 1888 to examine the flora and fauna of the West Indies

Of his more general writings undoubtedly the best known are the two volumes on insects in the "Cambridge Natural History," published in 1895 and 1899 respectively, which at once became standard works. His memoir (1912) written in collaboration with Mr. F. Muir on "the comparative anatomy of the male genital tube in Coleoptera" is a masterly treatise, on the production of which the breadth of his learning was brought to bear. In 1873 appeared his pamphlet on "the object and method of zoological nomenclature," in which he elaborated the view that nomenclature requires, for the maintenance of continuity of knowledge, fixed names for the species of animals, while changing ideas as to classification need shifting names for their expression. He advocated that the two names generic and trivial, originally given to an animal should always be preserved intact, even though it may subsequently be placed in several different genera at different periods. He held also that the analytic system of Linnaeus, in which species are treated as fractions of genera, broke down almost at once, and that only by a synthetic system could progress be made; that species must first be rightly understood, and then grouped into genera. These ideas he carried into practice in his monograph of the water-beetles, but in his later works he did not adhere strictly to the system of naming there used. In the introduction to that monograph he also expressed some of his views on the origin of species, an example of his cautiousness with regard to accepted ideas. He also discussed the phylogeny of insects in the proceedings of the Congress of Zoology held at Cambridge in 1898; and the senses, especially the sight, of insects in his retiring presidential address to the Entomological Society (1888). To him are due the articles on "Termites" and "Insects" in the volumes of the "Encyclopædia Britannica" issued in 1902, as is also (in part) that on "Hexapoda" in the later edition (1910).

Perhaps Dr. Sharp's greatest service to zoology was in connexion with the "Zoological Record." Of this he became general editor in 1892, and he only laid the work down a few weeks before his death. Throughout this period he was also recorder of all the literature on insects. He improved the volumes immensely, and raised the classified subject-index to a wonderful degree of efficiency.

So far allusion has been made only to his writings, but he also excelled as a field-worker and collector. Ever laying great stress on the importance of the collection and permanent preservation of material, he published several articles on these points. His collection of British Coleoptera is as fine as any, and he also made a very large foreign beetle collection, the greater part of which, consisting of some 150,000 specimens, was acquired by the British Museum in 1905. During his time at Cambridge he amassed a large amount of material for that Museum. His fine library was recently purchased by the Cawthron Institute at Nelson, New Zealand.

Dr. Sharp was a wide reader, and though of rather slight bodily frame he had, even to an advanced age, great powers of endurance as a field-worker, and an almost unlimited capacity for mental work. No time was ever lost in picking up the threads of his work, so that even short intervals were used to the full. He was Hon. M.A. of Cambridge; elected F.R.S. in 1890; fellow, and former councillor of the Zoological Society. He joined the Entomological Society in 1862 and was president in 1887 and 1888, besides holding lesser offices on several occasions. He was also an honorary or corresponding member of the New Zealand Institute and of the principal entomological societies of the world.

H. S.

Dr. William Kellner.

Dr. William Kellner, who died at Charlton, on September 12, in his eighty-third year, was born at Frankfort in 1839, and received his scientific training under Prof. Wohler at Göttingen, finally obtaining his Ph.D. degree in that university. He became a Fellow of the Institute of Chemistry in 1878 and served on the Council from 1895 to 1898. In 1862 he came to England as assistant to Sir Henry Roscoe, at Owens College, Manchester, whence, in 1864, he went to Woolwich and joined the staff of the War Department chemist (Sir Frederick Abel). In his early years at Woolwich Dr. Kellner was engaged in the varied general work of the chemical department. Later his main work became investigatory and experimental, both in connexion with explosives, as also to meet the requirements of the various Commissions and Committees on which the War Department chemist was a prominent member; of these the "Royal Commission on Accidents in Mines" and "The Explosives Committee" (appointed in 1889 to produce a smokeless powder for the Service) may be mentioned.

Dr. Kellner also devoted much work to the production of an apparatus for determination of the flashing point in oils, and was largely responsible for the Abel flash point apparatus, eventually perfected; in collaboration with Sir Boverton Redwood he carried out an exhaustive series of tests with this apparatus.

As a scientific worker Dr. Kellner was painstaking and methodical, displaying much skill in devising experiments to assist in elucidating the various problems confronting him in the course of his work. As regards practical results his most important work was in connexion with the evolution of cordite, much of the more difficult research and experimental work leading to the production of this explosive being carried out by him in the chemical department at Woolwich Arsenal; in spite of the numerous smokeless powders which have been brought into use since, the fact that, after a period of thirty years, cordite still remains the British Service propellant for army and navy use, is perhaps the best testimonial to the thoroughness of his work in this direction.

In 1892 Dr. Kellner succeeded Sir Frederick Abel as chemist to the War Department, and in addition to the duties of this office, served as an associate member of the Ordnance Board and as consulting chemist to the Royal Gunpowder Factory at Waltham Abbey; he retired from the service in 1904.

We much regret to announce the death on October 2, at fifty-eight years of age, of Col. E. H. Grove-Hills, F.R.S., formerly head of the Topographical Department of the War Office and the author of a number of papers on astronomical subjects.

Current Topics and Events.

H.R.H. the Prince of Wales has graciously accepted an invitation to be present at a joint dinner of the Institution of Mining Engineers (representing coal-mining engineering) and the Institution of Mining and Metallurgy (representing the mining of minerals other than coal) to be held on Thursday, November 16. The dinner will be held at the Guildhall by permission of the Corporation of the City of London.

In his presidential address to the British Association at Edinburgh last year, Sir Edward Thorpe referred to the difficulty which is encountered by many workers in science of being unable to obtain all the scientific books they require owing to lack of means. Sir Robert Hadfield has now generously offered to contribute a sum of 50*l.* per annum for three years, to be expended in supplies of books to those who are engaged in scientific pursuits and are unable to purchase for themselves. The council of the British Association has at present under consideration the best means of allocating this gift.

Among many important accessions of manuscripts to the Library of Congress (Washington) noted in the librarian's report for 1921, we observe the papers and correspondence of the late Major-General W. C. Gorgas, and the diaries and note-books of Jean Nicholas Nicollet, the explorer of the upper Mississippi, Missouri, Red, and Arkansas rivers in the first

half of the nineteenth century. The division of maps has received many rarities. An increase of receipts from the Central Powers is noted. A large number of these were theses of German universities and institutes of technology, which goes to show that the work of these institutions was carried on during the war without interruption."

ACCORDING to letters received by the last mail, the International Congress of Americanists at Rio de Janeiro has been a very great success. An enormous mass of papers was presented, all of which the Government proposes to print in full. At the close of the meeting the majority of the members took advantage of the delightful excursions which had been arranged for their benefit. After some discussion it was decided to hold the twenty-first session of the congress in 1924 in Holland by invitation of the Dutch Government, and in 1925 at Gothenburg, Sweden, by invitation of that town, where the museum is in charge of Mr Erland Nordenskiöld, the well-known authority on South America. In 1926 the congress will meet in Philadelphia.

THERE are welcome indications that the work of investigating our national antiquities, interrupted by the outbreak of the war, is now being revived The Congress of Archæological Societies, in union with the Society of Antiquaries, London, has just issued the first number, for 1921, of "The Year's Work in Archæology." This useful publication gives lists, arranged in the three kingdoms and their counties, of the progress of exploration. In a valuable supplement we have a list of the more important papers on the subject published by the local societies, and though a large number of these societies are affiliated to the Congress, there is still room for the association of local workers in this important enterprise The Congress makes an appeal for contributions in order to effect the purchase of Cissbury Ring, near Worthing. As this pamphlet shows, there are still considerable vandalism and destruction of important monuments; the Congress protests specially against the destruction of a portion of the Middlesex Grim's Dyke at Pinner Green, and other examples are quoted in the Report Much important work is being done in connexion with the Archæological Survey, and the president, Sir Hercules Read, remarks that there are many signs that we are at last becoming a civilised nation, as is shown by the Ancient Monuments Act and the appointment of the Congress Secretary, Mr. Crawford, to the newly created post of Archæology Officer at the Ordnance Survey.

THE *Toronto Star* of July 6 last has a note on a method of marking trails leading to springs of water which is practised by Indians of Western Texas. Two heaps of rock roughly heaped together, one about three feet high, the second a little lower, are placed beside the track, usually on an elevation commanding a view of the country for some five miles or more. A sight is taken from behind the larger heap, over the smaller, to some object on the horizon, such as a tree or clump of bushes. Near this object will be found a second pair of heaps of rock sighting on a second objective. This process is continued until the spring is reached. This primitive method of sighting a trail is of interest in connexion with the suggestions put forward by Mr. Alfred Watkins in his "Ancient British Trackways," recently noticed in these columns. He argued that many of the older roads in this country could be assigned to pre-Roman times on the evidence of what it was presumed were sighting marks, which must have been used in much the same way as the Indians are said to make use of these heaps of rocks. Mr. Watkin's theory, as was pointed out when it was under notice, undoubtedly holds good in many cases, especially in connexion with natural objects; in others, particularly in the case of mounds, moats, churches, etc, it appears more open to criticism

THE Fifth Annual Report of the Imperial War Museum has recently been issued by H M Stationery Office, price 9*d* (post free 10½*d*). It is typewritten on 8 folio pages and reproduced by a multicopier. This at any rate shows a desire for economy, calculated to appease the public The work of the museum during the year 1921-22 consisted in a complete survey of the whole collection, elimination of items of no technical value or historical interest, and the compression and concentration of the more valuable exhibits under definite headings and groupings This was particularly the case with the Munitions and Air Force exhibits. Stress is laid in this report on the technical value of the collections and on the fact that many objects of our everyday life during the War have been preserved in this museum while they have disappeared elsewhere. Allusion is made to the proposal to utilise two galleries at present occupied by the Science Museum and certain galleries now occupied by the Imperial Institute These proposals have, it will be remembered, evoked a great deal of opposition. The committee appointed to investigate on them has reported to the Cabinet, but no decision has yet been reached

DR DAVID STARR JORDAN proposes that the International Commission on Zoological Nomenclature should reject the following works from consideration under the Law of Priority —Gronow, 1763, "Museum Ichthyologicum"; Commerson (as footnotes in Lacépède, "Hist nat. des poissons," mostly 1803); "Gesellschaft Schauplatz," 1775-1781, an anonymous dictionary accepting the pre-Linnaean genera of Klein, Catesby, 1771, "Natural History of Carolina, Florida, and the Bahamas" (1731-1750), revised reprint by Edwards; Browne, 1789, revised reprint of "Civil and Natural History of Jamaica"; Valmont de Bomare, 1768-1775, "Dict. raisonnée universelle d'hist. nat." (several names accidentally binomial). By this all systematic names published as new in those works will be rejected as of the dates in question, but will remain available as of the dates when they were adopted by later authors of unquestioned status. It is hoped that the proposed action will extricate zoologists from an impasse into which they have been led by a divergence of views respecting the terms

"binary" and "binomial." Zoologists who may have opinions on this proposal, which they desire to lay before the Commission, are invited to communicate them in writing to any member of it, so that they may reach the Secretary at Washington, D C, U S A, before September 1, 1923 They would do well first to consult Opinions Nos 13, 20, 21, 23, and 24 issued by the Commission

THOSE who are familiar with the history of the elements will know, and those who are not familiar can easily inform themselves of the fact, that Lavoisier included among the elements both light and heat, which he classified along with oxygen, nitrogen, and hydrogen A more detailed study of his "Traité élémentaire de chimie" will show that before discussing the compounds of oxygen, nitrogen, etc, with other elements, he devoted a brief chapter to observations on the compounds of light and heat with different substances. The rapid development of chemistry soon led to the abandonment of these imponderable elements, which came to be regarded as different manifestations of energy It is, therefore, of interest to read in the *Pharmaceutical Journal* of August 12 a letter in which Mr Carol A Cofman Nicoresti, B ès Sc et Lett, announces, as a final conclusion of his investigation of gaseous volume and pressure, "that heat and light are both material substances, that they enter into chemical combination with other elements, and that they are *thrown out* by *chemical reaction*" It is perhaps a compliment to Lavoisier that even his untenable hypotheses should thus undergo resurrection, but that they should be put forward as original can only be taken as a sign of imperfect chemical education In one other respect Mr Nicoresti's growth as a student of chemistry appears to have been arrested at a period more than a century earlier than Lavoisier, since he asserts that after careful consideration he is driven to the conclusion "that there are no such things as *gases*, but that there is only *one* gas in nature That explains why the gaseous laws *are so uniform*" In this respect he apparently adopts the views of Boyle and Mayow, and his chemical education appears to have been carried forward but little further than the period of Agricola, who "hinted that the gases in mines were manifestations of malignant imps"

IN the will of Prince Albert of Monaco, who died on June 26 last, there are noteworthy gifts for scientific purposes His farm at Sainte Suzanne is left to the French Academy of Agriculture, and the wish is expressed that the estate should remain a place for agricultural experiments, to demonstrate what science and determination can obtain from sterile lands Dr Jules Richard will receive 600,000 francs to enable him to complete literary and scientific works in progress, including the results of the oceanographic cruises and the preparation of the Bathymetric Chart of the Oceans The proceeds of the sale of the yacht *Hirondelle*, all books and publications of a scientific nature, as well as certain personal effects, will go to the Oceanographic Institute at Paris and Monaco, while the Institute of Human Palæontology in Paris is to receive any personal effects relating to the work carried on there The Paris Academy of Sciences will receive a million francs, the income of which is to provide a prize to be awarded every two years, the nature of the prize to be indicated by the Academy, according to the needs of the moment; a like sum is bequeathed to the Academy of Medicine for a similar prize

WE learn from the *British Medical Journal* that the Carnegie Hero Fund trustees have awarded a medallion and an annuity of 130*l* to Dr. John Spence of Edinburgh, in recognition of his valuable and heroic work in radiology Dr Spence was among the first in Scotland to take up research in X-rays and medical electricity, and as a result of radiological experiments he sustained serious damage to both hands, necessitating amputation of the right forearm Dr Spence is still carrying on his work as radiologist at Leith Hospital and Craigleith Hospital, Edinburgh.

H R H THE DUKE OF CONNAUGHT has consented to unveil the roll of honour which has been erected at the Institution of Civil Engineers to the memory of its members and students who lost their lives in the war The ceremony will take place at 4 P M on Friday, October 27.

AT the next ordinary scientific meeting of the Chemical Society on October 19, Prof T M Lowry will read a paper entitled "The Polarity of Double Bonds An Extension of the Theories of Lapworth and Robinson," and it is hoped that a general discussion will take place On Thursday, October 26, at 8 P M, a lecture entitled "The Significance of Crystal Structure" will be delivered by Sir William H Bragg, in conjunction with Prof W L Bragg This meeting will be held in the lecture hall of the Institution of Mechanical Engineers, Storey's Gate, S W 1

WEATHER reports from Captain Amundsen's arctic expedition will be sent from the ship *Maud* and included in the collective message broadcasted by wireless from the Eiffel Tower daily at 11 h 30 m G M T These observations, according to the *Meteorological Magazine*, will commence on October 15

IT was announced at a meeting of the Chemical Society on October 5 that Prof J F Thorpe had been nominated to fill, until the next Annual General Meeting, the office of treasurer, rendered vacant by the resignation of Dr M O Forster, recently appointed Director of the Indian Institute of Science at Bangalore Dr J T Hewitt was nominated to fill the vacancy in the list of vice-presidents caused by Prof Thorpe's appointment

FROM the Report of the Castle Museum Committee to the Town Council of Norwich for 1921, just received, we learn that the Norwich Education Committee has appointed a special demonstrator to conduct round the museum organised parties of about 25 pupils accompanied by teachers During the year 19,801 attendances were recorded, each class attending the complete series of demonstrations in sixteen weekly

visits. The first lecture dealt with the purpose and methods of a museum, the next thirteen with various forms of animal life, the fifteenth with the early history of man, and the last with the story of the rocks and fossils. We understand that other Education Committees think of following this excellent example.

MR. H. E. STONE, of Sidcup, Kent, has forwarded to us a photograph of a specimen of *Datura Stramonium* which has attained a height of 28 inches with a foliage span of 58 × 24 inches, and bears 25 well-developed seed-pods. The plant is undoubtedly a fine specimen, although not unusually large. The largest plants are often found on rubbish-heaps made up of garden refuse, and also as weeds in cultivated ground. Such plants benefit by their isolation as much as by rich food material. Cultivated plants are often allowed to stand too close together to be able to develop to their full extent, while they usually lack the rich food material available in the case of isolated plants, and particularly those that have sprung up as weeds.

THE London agency of the Smithsonian Institution, Washington, which, since 1871, has been carried on by Messrs. William Wesley and Son, 28 Essex Street, Strand, London, has been removed to the premises of the new firm of Messrs. Wheldon and Wesley, Ltd. (incorporating William Wesley and Son), at 2, 3, and 4 Arthur Street, New Oxford Street, W.C.2. The large number of societies, museums, and institutions which forward their publications for transmission to their American correspondents through the International Exchange System of the Smithsonian Institution are requested to forward their consignments in the future to 2, 3, 4 Arthur Street, New Oxford Street, W.C. 2.

Our Astronomical Column.

THE SUNSPOT PERIODICITY.—Many attempts have been made to correlate the 11 year period of spot variation with the 11·86 year period of Jupiter's revolution. The latter, as it stands, differs too widely, and it is necessary to combine it with some other period. Prof. T. J. J. See, in a special number of *Astr. Nachr.*, vol. 216, attempts to combine it with 9·93 years, which is the period in which Jupiter gains a semi-revolution upon Saturn. He weights these two periods in the ratio 1·828 to 1, this ratio being the square root of that of Jupiter's mass to Saturn's mass. The result is 11·18 years, which is close to the sunspot period. But it is to be noted that while the 11·86 year period depends wholly on Jupiter, that of 9·93 years depends on both planets, so that the appropriateness of the above ratio is far from clear; apart from this the resulting period of two wave motions does not depend on the ratio of their amplitudes, but on the time that one takes to gain a revolution on the other. For example, the period from spring tides to spring tides is a semi-lunation, and this would not be altered by an alteration in the relative heights of solar and lunar tides.

It will be remembered that Prof. E. W. Brown also endeavoured to get the sunspot period from Jupiter and Saturn, though in a different manner. He was successful in predicting that the 1907 maximum would be a late one. Mr. E. W. Maunder directed attention to the cyclical shift of the spots in solar latitude synchronously with the variation in activity, which seems to indicate an internal rather than an external origin.

FLAMSTEED'S LETTERS TO RICHARD TOWNLEY.—This very interesting packet of letters was recently found at the Royal Society. Dr. Dreyer contributes a long article to the *Observatory* for September describing their principal contents. A few points may be mentioned here. Flamsteed was prompt in accepting Roemer's explanation of the annual inequality of Jupiter's satellites, due to the finite velocity of light. He studied refraction at low altitudes by measuring the change in the apparent vertical diameter of the sun.

We find from his notes on the great comet of 1680 that he was at that time still a believer in the vortices of Descartes, though he makes a note on Newton's different opinion. By 1686 Flamsteed had apparently become convinced of the overthrow of the system of vortices; after alluding to the progress in the printing of the "Principia" he expresses his satisfaction in the immense gain that the new system will afford in the study of the planetary motions, "so that in the room of mourning I congratulate my own happiness."

It is rather melancholy to note how his opinion of Halley gradually changed from admiration to jealousy and suspicion. This seems to have been largely due to the association of Halley with Hooke, whom Flamsteed considered an enemy.

We share Dr. Dreyer's hope that the letters will be published in full.

PERTURBATIONS OF WOLF'S COMET.—Allusion was lately made in these notes to the work of M. Kamensky on this comet from its discovery in 1884 to the present time, and to the large changes in its orbit likely to arise from the very near approach to Jupiter this year. He has now calculated these changes, and gives the results in *Astr. Journ.* No. 807. The least distance occurred on September 26, when it was one-eighth of a unit, so that Jupiter's direct action was 1½ times that of the sun, and the assumption of elliptical motion ceases to be the smallest approximation to the truth. On the other hand, a remarkable approximation may be obtained by assuming the motion to be in a hyperbola about Jupiter, which is equivalent to treating the action of the sun on the two bodies as identical during the time of near approach. Incidentally this gives an opportunity for using the equations for hyperbolic motion, which are given in the text-books but very seldom employed. The results obtained by this simple method are quite close to those of the more rigorous investigation. A curious point is that the present perturbations are about equal in size but opposite in direction to those at the approach of 1875, so that the comet now returns very nearly to its 1875 orbit. The period is increased from 6¾ to 8¼ years, and the perihelion distance from 1·53 to 2·40. It fortunately happens that at the next perihelion passage, 1925, Oct. 28·4, the comet will be almost in opposition, so that the distance from the earth will attain its minimum value, 1·40. Prof. Kamensky hopes that it may not be beyond visual or photographic reach with large instruments; if it should be found, most of the credit will belong to him; if not seen then it will almost certainly be permanently lost.

Research Items.

THE ROMAN BALANCE IN SOUTH AMERICA.—Mr. Erland Nordenskiöld has reprinted from the journal of the Société des Américanistes de Paris (N.S. vol. xiii., 1921) an article sub-entitled "Emploi de la balance romaine en Amérique du Sud avant la conquête." He produces evidence, with a full bibliography of authorities, to show that this invention was not confined to the Old World, but was found in the New World before the discovery of America.

ANTHROPOLOGY IN THE CHILTERN HILLS.—In the Journal of the Royal Anthropological Institute (vol. lii. Part 1), Mr. W. Bradbrooks and Prof. F. G. Parsons publish an elaborate memoir, with a long series of measurements of skull form, on the population of the Chiltern Hills, in which they arrive at the following conclusions: in this comparatively isolated area about half the working-class male people can trace their ancestry back to three generations in some part of the area; the hair colour is rather darker than Beddoe found in the Eastern and East Midland Counties, and the proportion is higher than in any other part of Great Britain, except the South-western Counties and Wales; the eye colour is identical with that of London and the East Midlands, the average cephalic index, 77.7, is practically that of the modern working man in London, and the average height, 5 ft. 7 in., is that of the black-haired individuals. Thus, the present-day inhabitants of the North Chiltern area, who are not recent immigrants, are distinctly darker haired than those surrounding them, and this darkness appears to be due to the survival of a great proportion of Neolithic or Mediterranean blood in the district.

DISTRIBUTION OF FUTURE WHITE SETTLEMENT.—The problem of the potentiality of the world for white settlement is attacked quantitatively by Dr. Griffith Taylor in the *Geographical Review* for July. The world is divided into economic regions which coincide in the main with Herbertson's natural regions. The areas of these regions are determined by planimeter measurements. The factors influencing human settlement are grouped under four headings which comprise the dominant controls—temperature, rainfall, location, and coal reserves. Fisheries have local rather than general importance and are ignored. From the values of each of these four controls a quadrilateral graph, the econograph, is constructed for each region, and the area of the graph is found to represent approximately the habitability of the region concerned. The econograph is a rectangular figure formed on four axes which represent, respectively, the average annual temperature, the average annual rainfall, the average elevation, and the estimated total coal reserve of the region. In what Dr. Taylor believes to be the ideal region these values would be 55° F., 50 in., sea-level, and 200×10^{1} tons per square mile. The comparative value of these controls was apparently reached by assuming various values and testing them against the actual population map of Europe. By this means Dr. Taylor decided to give the temperature control double the weight of the rainfall and allow the coal factor, if large, to have equal weight with optimum temperature and rainfall combined. The ideal econograph represents 1000 units. All the seventy-four regions of the world have values below this ideal. The last step was to plot on a map of the world the numbers representing the areas and draw lines of habitability, called isoikets. This map is of great interest as a partially successful attempt to forecast the future growth of white settlement.

MOSQUITO INVESTIGATIONS.—Since the statement was made by Messrs. Carter and Blacklock, that *Anopheles plumbeus* is a potential carrier of malaria in this country, it having been experimentally infected by them, considerable interest has been taken in the habits and distribution of the species in Britain. Following studies made by these authors in the Liverpool district and in the Isle of Man, an inquiry was instituted by the mosquito investigation committee of the South-Eastern Union of Scientific Societies, acting on behalf of the Ministry of Health. The committee now announces that this special inquiry is concluded, and that *A. plumbeus* has been shown to be exclusively sylvan in habits, and to be widely distributed in England, occurring, when searched for, in almost any area in which are found beech, sycamore, chestnut, or other trees with water-containing rot-holes. The committee is now turning its attention to the mating and egg-laying habits of *A. plumbeus* and other species, which are still imperfectly known, and invites co-operation from observers in all parts of the country in elucidating these matters.

MUSCARINE.—In the Journal of the Chemical Society for September, Dr. Harold King, of the National Institute for Medical Research, records the isolation of muscarine, the highly potent and toxic principle of *Amanita muscaria*, the Fly Agaric, a common fungus of our birch woods. Muscarine has been the fertile subject of controversy among chemists and pharmacologists for more than fifty years, and it is now shown that the pure material differs essentially from the original claims as to its properties and constitution made by Harnack, upon whose work the whole of the subsequent edifice has been erected. There is no evidence that muscarine is related to choline or is a quaternary base. More than ordinary interest is attached to muscarine owing to its extreme specificity of localisation in the mammalian body and its complete antagonism by atropine.

A NEW SPECTRO-POLARIMETER.—Messrs. L. Bellingham and F. Stanley, Ltd., of 71 Hornsey Rise, have designed and provisionally protected a polarising prism which can be used either in the visible or ultra-violet region of the spectrum. The prism is constructed from one solid piece of Iceland spar cut in such a manner with respect to the crystallographic axis, and of such a length of side, that the extraordinary ray only is transmitted while the ordinary ray is absorbed at the sides. Two such prisms are placed side by side in a suitable mounting. Before being placed in contact the sides of each prism are ground away to give the required length of dividing line between the halves and also to produce the necessary half shadow angle. To provide a sharp face edge one of the prisms is allowed to project in front of the other, and the two are then bound together. It is claimed that such an arrangement is absolutely permanent and that the extinction is perfect. The entire absence of cement relieves the prism of all strain, and eliminates the possibility of light being diffused from particles in the cement or from scratches on the cemented surface. By employing such a polarising prism Messrs. Bellingham and Stanley have been able to construct a polarimeter which can be used either for visual observation, in conjunction with a mercury lamp, or for photographing the entire spectrum between wave-lengths 230 $\mu\mu$ and 800 $\mu\mu$ at one exposure.

The Fauna of the Sea-Bottom.[1]

By Dr. C. G. Joh. Petersen, Director of the Biological Station, Copenhagen.

STUDIES of the fauna of the sea-bottom are of essential zoological significance, and many scientific questions as well as important fishery interests depend upon them. The subject, however, is so extensive that I must confine myself mainly to the different methods adopted for the investigation of the fauna of the sea-bottom.

Since 1883 I have investigated Danish waters by means of the dredge; it was my task then to give on charts the distribution, especially in the Kattegat, of every single species of marine animal, to understand the laws ruling the distribution of the animals on the sea-bottom (the cruises of the gunboat *Hauch*). Different specialists had each a group of animals to work out, and a great number of charts were printed, but I did not feel quite content with my first publication, although something was cleared off by that method. The method was, and is still, the usual one for such investigations.

Many years later the question was put before me: Why does the plaice in the western Limfjord grow very slowly, but very quickly in the middle of the Limfjord? The answer required first of all a quantitative investigation of the amount of plaice-food in both places. A small bottom-sampler on a pole, long enough to reach the bottom in the shallow fjord was made in the 'nineties of last century and proved that much food was to be found in both places; the difference in growth-rate of the plaice was found later on to depend not only upon the amount of food on the bottom, but also upon the different number of plaice living there on each square mile. The idea of overcrowding for sea-fishes was introduced for the first time.

Many years later I constructed a new bottom-sampler fastened to a wire; this I have used everywhere in Scandinavian waters down to a depth of 300 fathoms. It was my idea at first to compare the amount of fish-food per sq. metre in the Limfjord with the amount of fish-food per sq. metre in our remaining waters by means of the bottom-sampler; but I soon found it difficult to compare the animals from one water with those of another; in some places the animals were small and of great value for fishes, in others the animals were bigger and built up of carbonate of lime (chalk) mainly, and with a great content of water; chalk and water being of course of little importance as food in the sea for other animals, I realised that I should compare, first of all, the amount of food in places with the same kind of animal population, and I had to map out these places.

The bottom-sampler taught me that we have about eight such different animal communities in Danish waters from 0 to 300 fathoms, characterised by numerous large and characteristic animals. They may be echinoderms, bivalves, crustacea, etc., but are all animals living mainly on detritus, not rapacious animals. These last named are necessarily always scarcer than the more peacefully living animals, as the grass-feeding animals on the dry land are more common than tigers and lions.

One thing puzzled me in the beginning very much; the bottom-sampler showed in many hauls the most uniform content in the sieves in the same animal community, then suddenly it came up filled with quite different animals, *Modiola modiolus*, Trophonia, *Ophiopholis aculeata*, etc., without any corresponding difference in the depth or in the nature of the bottom. How is this to be explained?

All these new organisms were animals living not in the bottom like ordinary animals, but above the bottom, originally fixed to a small stone or a shell, as on a heath we may find lichens on stones, not heather, or as in a beech-wood, on stones we find mosses, not flowers; strong currents may help to nourish such an *epi-fauna* with its often enormously rich animal life. Every object on the sea-bottom, a stone, a shell, a wreck, living plants, may give rise to such epi-faunas; within the same community on the level sea-bottom there is the same epi-fauna, but in different communities different epi-faunas may be found. The epi-fauna is, as a rule, scattered over the bottom in spots, and it is not always easy, in single cases, to say what is the reason for its existence; it is therefore not possible to give its distribution on a chart; you may give it on the spots where you have found it, but you never will be able to give all the spots existing on the bottom. On rocky coasts the epi-faunas are dominating; the coral reefs are a kind of epi-fauna, built up mainly of chalk and water; they are of very little importance as fish-food.

In contradistinction to the distribution of the epi-faunas the communities of the level sea-bottom are of a very uniform distribution, in such localities as in Danish waters and in the North Sea. Their distribution may be easily mapped out, and their content of fish-food and other animals quantitatively determined. We have taken thousands of samples, each of $\frac{1}{10}$ sq. metre, with the bottom-sampler in Denmark, and they have nearly always shown several animals, worms, bivalves, Ophiuridæ, etc., in each; only one or two samples of them have shown no animal content.

By means of the bottom-sampler we may, therefore, using the most frequently occurring organisms, easily map out the communities of the level sea-bottom, and determine its content of fish-food.

The theory of probability will indicate the degree of accuracy; many samples will give, as a rule, more and more exactitude. We may determine how the number of organisms varies at different seasons and in different years. If we examine what the fishes eat of these organisms we may determine whether they are good or bad areas for this or that species of fish, and may get a fair idea of the productivity of the sea-bottom as a whole, not forgetting that all the small, fast-growing, short-living animals are often to be reckoned as yearly production, whereas the bigger, longer living animals must be reckoned by means of another method. We may get an idea of the whole metabolism of the sea—but I must not go too far in mentioning these problems.

With a good steamer I could in one month map out the whole of the North Sea as to its animal communities. I would take between 500 and 1000 samples spread over the whole of the North Sea, out to the 100-fathom line, about one or two per hour. Using a bottom-sampler of 0.2 sq. m. I should then have taken up only the animals of an area at 100-200 sq. m., but I am sure that I should get all the species of the common uniformly-distributed animals of the whole area, and I should be able to give a rough-sketched map of the animal communities. If we used a bottom-sampler on a heath only once, we should catch heather, and so in the sea, I should not catch many rare animals, but I do not care for rare animals; the main thing is to know the animals that make up the great bulk of the bottom population, to know their distribution and their weight per square mile. If you wish for greater exactitude than

[1] Opening of a discussion held in Section D (Zoology) of the British Association at Hull on Sept. 7.

this first trip could give, you may take more stations and investigate smaller areas more carefully.

I am glad to be able to say that in 1921 Dr. Russell, on the English steamer *John Bligh*, made the first trip across the North Sea with my bottom-sampler, guided by my assistant, Dr H Blegvad, they found some of the same communities between Lowestoft and Esbjerg as we know from the Kattegat.

Thanks to the bottom-sampler we can now speak about areas with a Venus mussel community, an *Amphiura filiformis* community, a *Brissopsis Amphiura chiajei* community, and so on, as we on land speak about a heath, a beech-wood, a meadow, etc; we are also able to get a quantitative idea of the amount of animals on the sea-bottom, and are able to follow seasonal or other variations therein

A dredge will sometimes give us, when well used, a bagful of animals, belonging to the epi-fauna as well as to the ordinary communities, and taken up from all the communities it has been towed over. The dredge is inclined, moreover, to take all animals *on*, not *in*, the bottom, and its content is therefore not a true illustration of what is living *in* or *on* the bottom, but a mixture mostly of epi-fauna from different communities, without giving the slightest idea of quantity per square metre. The content of a dredge and a bottom-sampler used on the same station will very often give quite different collections of animals

The dredge has given excellent information to zoologists wishing to collect rare animals for preservation in alcohol, and for dredging oysters, and so on, but a true illustration of the fauna on the sea bottom it never has given and never will give

I admit one thing it is easy for me to speak and write about the bottom-sampler work, but it never will be well understood without seeing the work going on on board ship, many men of science from Europe have seen how quickly the sampler may be used, like an ordinary sounding machine, and how well it works I should be glad to welcome many more visitors at the Danish Biological Station, not only to see the bottom-sampler working, but also to be able to discuss with them the problems which have arisen in my mind while using this method during the last 10 to 12 years

It was a Dane, O Fr Muller, who first introduced the dredge in northern Europe for scientific use, and it will always be used by zoologists and for special purposes, but only the bottom-sampler is able to give a true and quantitative representative illustration of the bottom fauna.

Finally, I wish to say that to have a bottom-sampler and to use it is not enough to become a great marine biologist, it depends much upon the possession of working ideas. The bottom-sampler is not able to solve every question, it cannot, *e g*, take animals living very deep in a hard bottom, and the apparatus must be modified for special work, according to the size of the ship used, the depth at which you are working, etc, and it is necessary to supplement the investigation by means of other apparatus, fishing-gear, dredges, etc But without quantitative work it is not possible to understand the principal features of the fauna of the sea-bottom

It would be a matter of great scientific interest to have a bottom-sampler used down the slope of the continent at all depths, out on the very ocean floor, to determine all the communities living here, and to prove how barren the ocean floor really is It would also be of great interest to follow our European communities from the North Pole down to Cape Town, to study their geographical distribution, to determine the perfectly unknown Arctic communities, and the unknown tropical communities I have given a hypothetical chart in my Report No 22, but it has to be verified I am too old to do that, and my steamer too small I hope other men will do it. I am sure the geologists would be glad to know something about these communities, based upon the common animals I am certain that, like me, they care much more for common characteristic species and their distribution than for "rare" animals

The productivity of the bottom fauna in European waters is by no means unlimited, it is, therefore, a matter of the greatest importance for some of the greatest fishery questions to know as much as possible about this productivity The English fishermen are, as I often have heard, the backbone of the English navy, they depend upon the fishes, and these in turn depend upon the fish-food Careful investigation of the latter is, therefore, a matter of great importance—particularly for Great Britain

---

Adhesives.

By EMIL HATSCHEK

THE treatise of Theophilus Presbyter, entitled "Diversarum Artium Schedula," and well known to all students of the history of painting, gives directions for the preparation and use of glues from leather and deers' antlers, of plum- and cherry-gums, and of mixtures of cheese and lime described as "cheese glues" This list of adhesives familiar to craftsmen at the end of the eleventh century covers practically all the types in use at the beginning of the twentieth century A similar degree of old empirical perfection is shown by many arts employing colloidal material, and the student of colloid chemistry anxious to magnify his office is perpetually confronted with the task of explaining the *rationale* of traditional procedure and of suggesting improvements based on theoretical grounds

The difficulties of this task are well illustrated by the first report of the Adhesives Research Committee[1] Towards the end of the war a shortage of glue and of the chief substitute, casein, threatened to limit the output of aircraft, and the labours of the committee were accordingly directed, on one hand, to a close study of glue, and, on the other, to the discovery of possible substitutes other than casein The report contains much interesting and novel matter under both heads

The difficulties in the way of a rational study of glue seem to be twofold The first is that the only criterion of its value as adhesive is a mechanical test of a glued joint between wooden test pieces of specified nature and size The report describes the conditions of such a test, as finally adopted, and sets forth the possible sources of error Both on theoretical and on practical grounds (about five days have to elapse from the soaking of the glue to the actual breaking test), it is desirable to find some easily measured constant which shows a simple quantitative relation with the breaking strength No such constant is yet known, although empirically the setting time of the glue sol, the melting point of the gel and its "strength," *i.e* roughly speaking, its modulus of elasticity, furnish some indication of its quality.

The second difficulty is of a more fundamental nature. It is known that pure gelatin is not a good

[1] Department of Scientific and Industrial Research "First Report of the Adhesives Research Committee," pp. iv+129 Price 4s

adhesive, so that the superiority of glue must be due, directly or indirectly, to the presence of other substances of which, so far, little is known. Investigations on this point are proceeding; in the meantime the committee have evolved a novel and highly promising test, that for "diffusible nitrogen." A gel of standard composition is immersed in a known volume of water, and after a fixed time the nitrogen content of the latter is determined by Kjeldahl's method. This is, of course, due to compounds of much lower molecular weight or aggregation than gelatin, and—apart from some exceptions—the amount of diffusible nitrogen is roughly inversely proportional to the tensile strength. While this result is of great interest, it can scarcely be said to simplify the problem stated above, namely, what factors cause the difference between pure gelatin and glue. Speaking, however, quite generally, we know of no connexion between constitution and adhesive properties; the striking fact is how sparingly the latter are distributed between a very few materials even among highly hydrated colloids.

Lack of space forbids detailed reference to the very interesting investigations on the extraction of gelatin from various raw materials, but the committee's successful attempt to find a strong vegetable adhesive must be mentioned. A protein was prepared from castor bean residues—which are poisonous and therefore useless as cattle food—and this protein forms a strong adhesive with calcium hydroxide and alkaline salts in various proportions. From the data given regarding the solubility of this protein, it appears to be related to casein, and the mechanical properties of the adhesive prepared from it are not much inferior to those of casein glues.

The report is supplemented by an appendix—which greatly exceeds in length the report itself—giving a "Descriptive Bibliography of Gelatin." This is a very complete, lucid, and impartial summary of the vast literature, in which no paper of any interest seems to have been overlooked. Those from English sources—though important—are remarkably few in number, and this state of things suggests questions which are none the less curious for being familiar. One is whether the development of a very promising discipline is going to be left to workers of other nations as completely as was (to take an unhackneyed instance) that of the theory of functions; the other, whether such cases of neglect arise from deep-seated national tastes or idiosyncrasies in research, or merely from inadequate opportunities for tuition and experimental work.

The Decomposition of Tungsten.

THE September issue of the Journal of the American Chemical Society contains an account of the preliminary experiments made by Drs. Wendt and Irion on the decomposition of tungsten at extreme temperatures, with the production of helium, a report of which appeared in the daily press, to which reference has already been made in NATURE (April 1, 1922, vol. 109, p. 418). The authors regret the exaggerated early report, given wide publicity by the press after its oral presentation, and emphasise the preliminary character of the work. They describe fully the apparatus used for attaining temperatures above 20,000° by passing heavy currents through metal wires, and state that when tungsten wires are exploded in a vacuum at such temperatures the spectrum of helium appears in the gases produced. When the explosion is conducted in carbon dioxide, 0.713 milligram of tungsten gave rise to 1.01 c.c. of gas not absorbed by potash solution. The authors remark that their method "includes factors, both of cause and of error, analogous to those operative in the voluminous and inconclusive controversy on the evolution of helium in various types of low pressure electrical discharge tubes, extending from 1905 to 1915."

The electrical apparatus provided for currents of 40 amperes at 100,000 volts during the brief period necessary to charge the condenser, which was then discharged through a tungsten wire 0.036 mm. diameter and 4 cm. long. The wires were stretched between heavy copper terminals in a special spherical glass bulb of 300 c.c. capacity, which was capable of withstanding momentarily an enormous outward pressure, and had a small discharge tube sealed on for examination of the spectrum of any gas produced. The wire was heated to well above 2000° for 15 hours in a high vacuum before the explosion was made, and the tube before explosion showed no spectrum or fluorescence when connected with a 50,000-volt coil. No dust, smoke, or solid residue was left after the explosion. Gas was present, which showed the faint presence of the strongest green line of mercury, probably from back diffusion of the pumps, and the only other line uniformly present and positively identified was the strong yellow line of helium. It would seem that both hydrogen and neon were absent. The absence of hydrogen is of interest, since the atomic weight of tungsten is exactly 46 times that of helium, and this element would therefore not be expected to give hydrogen on disruption of its atom.

The explosion in carbon dioxide seems to have been less conclusive, as the authors do not seem to have been quite sure of the absence of unabsorbable impurities. They point out that if the entire weight of 0.713 milligram of tungsten had been converted into helium, 4 c.c. of this gas should have been obtained. The much smaller volume found would point to the production of heavier gases. Altogether the work is of very great interest, although the authors emphasise the necessity of complete analysis of the gas obtained before anything conclusive can be stated. This chemical test is to be made in the continuation of the work.

The Belt of Political Change in Europe.

IN a paper contributed to Section E (Geography) of the British Association at Hull, Prof. J. F. Unstead commented on the striking fact that the new states of Europe, or those which have gained or regained independent existence during recent years, lie in a relatively narrow belt of country extending across the whole of Europe from the Arctic Sea in the north to the Mediterranean in the south. West of this belt changes have been slight, while east of it a final settlement has not been reached. Of this belt no part has been exempt from change. It contains about 100 millions of people or about one-fifth of the inhabitants of Europe, and covers about one-fifth of the total area of the continent. The new states have been formed mainly by the break-up of three great empires, the disintegration of which was one of the results of the world war.

Prof. Unstead pointed out that the belt of change is a region caught between east and west, marginal to each and influenced by each, and he showed how

this idea applies both to physical and human conditions. Western Europe, with inland seas and intricate structure and relief, provides varied resources, maritime, agricultural, and mineral Into this region spread the civilisation of the Mediterranean region, and here communities found the physical conditions which enabled them to develop. Physical barriers and relatively small productive areas gave distinctiveness and led eventually to the growth of separate nationalities. These nations became self-governing and, broadly speaking, democratic

Eastern Europe, on the other hand, is characterised by uniformity of structure and relief, with great belts of similar climatic conditions and natural vegetation extending through it into Asia and so facilitating human migrations and military movements, mainly east and west. From the human as well as the physical point of view this region was for many centuries an extension of Asia and had but a scanty population. The Slav languages became characteristic and the authority of the Czar dominated the greater part of the region. The Asiatic incursions which in earlier centuries swept across the eastern plains were as a rule checked when they reached the belt of change Here they found varied conditions of life, but different from those to which they had been accustomed Traditions and names of invading tribes have been preserved, differences of language remain, and not infrequently feelings of hostility and memories of conquest are rife. Sufficient time has not yet elapsed for a complete fusion of races in the several regions of the belt The Asiatic elements still assert themselves: Finns, Ests, Magyars, Bulgars, and Turks stand out, contrasted in one way or another with Swedes, Germans, Slavs, Albanians, and Greeks of European descent Moreover, two small Nordic groups, Letts and Lithuanians, have preserved their identity from early times and remain distinct from other Nordic people in language and nationality On the other hand, the occurrence of minerals has led to the partial penetration of Western influences

Prof. Unstead went on to show the diversity of religion and political conditions in this belt of change The problem of minorities exists in one form or another throughout the belt, and is perhaps the greatest menace to future peace The present political units are by no means self-sufficing, and their frontiers are frequently barriers to trade and hindrances to production Furthermore, the attainment of political freedom has often been accompanied by a check to production, commerce, and prosperity

University and Educational Intelligence.

ABERDEEN —Applications are invited for the Blackwell Prize, value 30 guineas, for an essay on "The Sculptured and Inscribed Stones of the North-East and North of Scotland" The essays, bearing a motto and accompanied by a sealed envelope bearing the same motto and giving the name and address of the writer, must reach the secretary of the university on or before January 1 next.

CAMBRIDGE.—Mr J. Walton, St John's College, has been appointed junior demonstrator of botany Mr. F. A. Potts, Trinity Hall, has been reappointed demonstrator of comparative anatomy Dr. A B Appleton, Downing College, Mr D G Reid, Trinity College, Mr A Hopkinson, Emmanuel College, and Mr. V. C Pennell, Pembroke College, have been reappointed demonstrators in anatomy Dr Ff. Roberts, Clare College, Mr. T R Parsons, Sidney Sussex College, have been reappointed demonstrators in physiology. Mr. G. V. Carey, Clare College, has been appointed educational secretary to the Cambridge University Press.

A. J. Smith, Downing College, has been appointed University Frank Smart Student in Botany. The John Winbolt prize has been awarded to F. E. Smith, Sidney Sussex College.

LEEDS.—Mr Lascelles Abercrombie, lecturer in poetry at Liverpool University, has been elected by the council of the University professor of English language and literature, in succession to Prof. Gordon, who was recently appointed to the Merton professorship of English literature at Oxford.

LONDON —It was announced in NATURE of July 29, p. 166, that Mr. H. G. Wells had consented to offer himself as Parliamentary candidate for the University, at the invitation of the executive of the University Labour Party, upon the retirement of Sir Philip Magnus at the end of the present session of Parliament. At a general meeting of the party held on Friday, October 6, Mr. Wells was adopted as Parliamentary candidate as recommended by the executive.

IT is announced that Mr. H. M. McCreath, head of the Agricultural Department, Seale-Hayne College, Devon, has been elected principal of the East Anglian Institute of Agriculture, Chelmsford.

A SITE consisting of nearly 20 acres has been presented by Mr T. R Ferens at a cost of about 10,000*l.* to the education authorities of Hull for the immediate purpose of providing accommodation for advanced technical departments It is anticipated that a university college will be developed later on the site.

THE distribution of geographical teaching in the universities of Europe is illustrated in a map which accompanies a paper by Mr W. L. G Joerg, in the *Geographical Review* for July, on "Recent Geographical Work in Europe" From this map it appears that more than 120 universities in Europe (excluding Russia and allied Soviet states) have provision for geography Germany, Switzerland, and France are perhaps the best provided, but Great Britain does not fall far behind In Balkan lands, geography is fairly well represented in Bulgaria and Yugo Slavia; Rumania has four universities offering geography, while Hungary and Czecho-Slovakia also have centres of instruction On the whole, the new or reconstructed states of Europe show every indication of realising the importance of the subject The only states in Europe which would appear to offer no university geography are Latvia, Lithuania, Albania, Greece, and Ireland

DURHAM University has recently published a calendar for the year 1922–23 (price 3s 6d net), a useful compilation which serves as a guide to affairs in the University. The first half of the volume deals with the University as a whole, its officers, the regulations affecting conduct and degrees, as well as the subjects required for the latter and for various diplomas are given. A special section is devoted to the fellowships, scholarships, and prizes which are awarded by the University. The remainder of the calendar is divided into three sections referring to the Durham colleges, the College of Medicine, Newcastle-upon-Tyne, and Armstrong College, respectively. It should be noted that up to and including September 1923 the matriculation examination will continue to be held in Durham and Newcastle; after October 1923 the matriculation examination (Newcastle Division) will cease to be held. The new regulations for matriculation in the Newcastle colleges, which will then come into force, are given in detail. In a concluding section of the volume there is an alphabetical list of members of Durham University.

Calendar of Industrial Pioneers.

October 15, 1889. Sir Daniel Gooch died.—An eminent locomotive engineer and industrial administrator, Gooch served an apprenticeship in Stephenson's works at Newcastle, and at the age of twenty-one became locomotive superintendent to the Great Western Railway. He invented the Gooch link gear, experimented on the resistance of the atmosphere to trains in motion, designed a self-registering dynamometer, and built many fine broad-gauge engines. After resigning his position, he played an important part in the establishment of telegraphic communication between England and America, and from 1865 to 1887 was chairman of the Great Western Railway.

October 17, 1907. Gustav Adolf Zeuner died.—Born in Chemnitz, November 30, 1828, and educated at the Mining Academy at Freiberg, Zeuner as a professor of engineering did important work at Zurich, Freiburg, and Dresden, while his writings were highly valued by engineers. He founded the German journal *Zivilingenieur*, and he was widely known for his works on value gear and on technical thermodynamics.

October 18, 1903. Gordon McKay died.—The most successful inventor of boot-sewing machinery, McKay, who was born in Massachusetts in 1818, made an immense fortune which he bequeathed to Harvard University for science professorships and laboratories

October 18, 1918. Marcel Deprez died.—For nearly forty years Deprez devoted himself to the application of electricity to industrial purposes He solved many of the problems connected with the transmission of high-tension electricity, invented the compound winding for dynamos and devised measuring instruments From 1890 he was professor of industrial electricity at the Conservatoire des Arts et Métiers.

October 19, 1749. William Ged died.—The inventor of stereotyping, Ged was born in 1690 and became a goldsmith in Edinburgh. In 1725 he took out a patent for developing Van de Mey's idea of substituting for movable type solid plates cast from type, and four years later he endeavoured without success to introduce his methods in London. His subsequent career was one of disappointment, and he died in poverty.

October 19, 1897. George Pullman died.—Pullman, to whom the world owes the modern railway carriage, was born in 1831 in New York State, and in 1859 settled at Chicago, where he began experimenting on the construction of sleeping-cars, his first successful car, the "Pioneer," being built in 1863 at a cost of 3000*l*.-4000*l*. The Pullman Palace Car Company was founded in 1867; extensive works were laid out in 1879, and at the time of Pullman's death more than 15,000 men were employed in them. The sleeping-car was introduced into England in 1875.

October 21, 1896. James Henry Greathead died.—Trained as a civil engineer under Barlow, Greathead devised the "Greathead" shield, which has since been extensively used for driving tunnels

October 21, 1902. Sidney Howe Short died.—Regarded as one of the most brilliant electrical engineers of his day, Short was a native of Columbus, Ohio, where he was born, October 8, 1858. Educated at the Ohio State University, at the age of twenty he succeeded Mendenhall as professor of physics there, and two years afterwards removed to Denver, Colorado. Resigning his chair in 1885, he took up practical work and did pioneer work in connexion with electric railways. E. C. S.

Societies and Academies.

SWANSEA.

Institute of Metals, September 22.—F. L. **Brady**: The structure of eutectics An attempt has been made to correlate the micro-structure of solidified eutectics, mainly those between metals and metallic compounds, with the physical properties of the component metals. The surface tension of the molten metal and the cohesive force acting during crystallisation seem to be the main forces influencing the final structure. The eutectics examined fall into three classes, "globular," "lamellar," and "angular" The structures agree with what would be expected from theoretical considerations of the effects of surface tension and cohesion.—M **Cook**: The antimony-bismuth system. The two metals form an isomorphous series of alloys. The liquidus curve is perfectly smooth and the solidus is horizontal at 270° C. up to 60 per cent. of antimony, after which it rises steeply to the freezing-point of antimony. Chill-cast and slowly cooled specimens reveal duplex structures, but with prolonged annealing—550 hours at 275° C.—the alloys become homogeneous. Twin crystals and peculiar banded effects were observed in some of the annealed specimens. Possibly the twin crystals are formed during solidification of the alloy by stresses due to expansion, and grew on annealing The nature of the "bands" has not been definitely ascertained, though they are not considered to be slipbands —A **Jefferson**. The cause of red stains on silver-plated work. The Sheffield Silver Trade Technical Society appointed a committee to examine this subject It was established experimentally that the red stain is caused by the indiscriminate use of rouge in the finishing and polishing processes, through the absorption of the rouge into the open pores of the heated surface, the heat being evolved by the friction of the hand or finishing "dolly" —Q A **Mansuri**. Intermetallic actions The system thallium-arsenic By thermal and microscopic analysis it was shown that thallium and arsenic do not act chemically with each other nor do they form solid solutions, they alloy in all proportions. Arsenic dissolves in molten thallium and lowers its freezing-point until a solution of 8·01 per cent arsenic freezes at the eutectic temperature of 215° C Then the freezing-points of the alloys rise gradually to 240° C. All alloys containing from 13 to about 40 per cent arsenic begin to freeze at 240° C and are made up of two layers—the upper layer rich in arsenic while the lower rich in thallium. Beyond 40 per cent arsenic, to nearly pure arsenic, the solution is uniform and the two layers disappear. By heating such substances in evacuated, sealed glass tubes and applying the hot junction of the couple in close contact with the outside of the glass tube, the couple is almost as sensitive as when dipped in the molten substance. —F **Johnson** and W. **Grantley Jones**: New forms of apparatus for determining the linear shrinkage and for bottom-pouring of cast metals and alloys, accompanied by data on the shrinkage and hardness of cast copper-zinc alloys. The shrinkage values of chill-cast copper-zinc alloys were higher in general than those obtained for sand-cast bars by previous investigators Pure electrolytic metals were used, and most of the alloys were poured at a temperature interval of approximately 115° C. above their liquidi, the mould being kept at a constant temperature by a jacket of water maintained at the boiling-point. The bottom-pouring apparatus has the advantage of (*a*) control of pouring temperature; (*b*) facility for registering temperature of metal; (*c*) absence of delay between attainment of required pouring-temperature and release of metal into the

mould, (*d*) control of rate of pouring; (*e*) exclusion of dross from stream of metal, and (*f*) mitigation of "zinc-fume." Uniformity of hardness was secured by annealing. For the annealed bars the Brinell curve showed an increase of hardness over the range 100 to 88 per cent copper From 88 to 72 per cent. copper hardness was constant, a slight fall setting in at about 72 per cent. copper and persisting to 63 per cent, at which point a rapid increase set in with the appearance of the β-constituent With the exception of a small dip in the curve, between 53 and 50 per cent copper, the increase is maintained to 45 per cent copper. The changes of scleroscopic hardness with composition are similar but less pronounced The hardening capacity of the α-brasses under cold-work increases rapidly with increase of zinc up to a maximum near 75 per cent. copper. The rolled strips after close annealing, were re-tested for hardness, the range of uniform hardness is slightly restricted and the succeeding fall (between 70 and 63 per cent copper) is more pronounced — F W **Harris** The hardness of the brasses, and some experiments on its measurement by means of a strainless indentation The theories generally advanced with regard to the connexion between hardness and internal constitution have been, in the main, substantiated A slight maximum occurs in the middle of the α-phase and a small depression in the β-phase The "absolute" hardness for the series was compared with the Brinell hardness by means of curves

PARIS

Academy of Sciences, September 11 — M L. Maquenne in the chair — L **Cuénot** and L **Mercier**: The loss of the faculty of flight in parasitic Diptera The hypothesis generally admitted is that the atrophy of the wings is the result of non-usage connected with the parasitic mode of life The authors give the results of a series of observations directly opposed to this view —E **Merlin** A mobile space attached to a network —P **Urysohn** Cantorian multiplicities D **Riabouchinski** The equations of motion in two dimensions, of solids in a liquid with vortices — Henri **Villat** Plane vortex movements in a fluid containing solid walls — M **Thiébaut** The composition of the iridescent marls These marls contain three main constituents carbonates (dolomite and calcite), a silicate which is not a clay, approaching celadonite and bravaisite in composition, and detritic elements with abundance of white mica and quartz W J **Vernadsky** The problem of the decomposition of kaolin by organisms In admixture with bacteria, diatoms developed well on a nutritive medium, containing no silica except combined silica in a colloidal clay From these results it would appear that diatoms, either alone or in association with bacteria, can decompose the kaolin structure and set free alumina — Cam **de Bruyne** Idioblasts and diaphragms in the Nymphaeceae — Marc **Romieu** A method of selective coloration of the nervous system in some invertebrates Details of the application of the benzidine-hydrogen peroxide reagent to the study of the nervous system of some invertebrates The nerves are coloured blue, and the nervous system as a whole can be seen down to the smallest details — Gabriel **Bertrand** and M **Mokragnatz** The presence of cobalt and nickel in plants The ashes from twenty species of plants have been analysed, the parts utilised as food being chosen for examination. Nickel has been found in all the plants examined in quantities between 0·01 milligram and 0·2 milligram per kilogram of fresh material: cobalt (0·005 to 0·3 milligram per kilogram) was found in all cases except oats and carrot.

Diary of Societies.

MONDAY, OCTOBER 16

FARADAY SOCIETY AND THE BRITISH COLD STORAGE AND ICE ASSOCIATION (at Institution of Civil Engineers), at 2 30, 4 45, and 7 45 — Discussion on the Present Position of the Generation and Utilisation of Cold — Prof H Kamerlingh Onnes and others: Laboratory Methods of Liquefaction, and Methods of Measuring Low Temperatures — Dr Crommelin Description of the Equipment of the Cryogenic Laboratory at Leyden — M Claude The Industrial Manufacture of Hydrogen by the Partial Liquefaction of Water Gas — E A Griffiths and others

CHEMICAL INDUSTRY CLUB (at 2 Whitehall Court), at 8 — Annual General Meeting

ROYAL GEOGRAPHICAL SOCIETY AND THE ALPINE CLUB (at Central Hall, Westminster), at 8 30 — Gen Bruce, Col Strutt, Mr Mallory, Capt. Finch, and Major Norton: The Mount Everest Expedition, 1922

TUESDAY, OCTOBER 17.

ROYAL HORTICULTURAL SOCIETY, at 3 — R G Hutton: The Control of the Fruit Tree by its Roots

ROYAL SOCIETY OF MEDICINE, at 5 General Meeting of Fellows

INSTITUTE OF TRANSPORT (at Institution of Electrical Engineers), at 5 30

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 8, —Major F C V Laws The Progress of Aerial Photography.

WEDNESDAY, OCTOBER 18

ROYAL COLLEGE OF PHYSICIANS, at 4 — Dr A Chaplin Harveian Oration

INSTITUTE OF PHYSICS (at Institution of Electrical Engineers), at 6 — C C Paterson The Physicist in Electrical Engineering (Lectures on "Physics in Industry," No 3)

ROYAL MICROSCOPICAL SOCIETY, at 8 —Prof R Chambers New Apparatus and Methods for the Dissection and Injection of Living Cells T F Connolly The Specification of a Medical Microscope H J Denham A Micrometric Slide Rule.

THURSDAY, OCTOBER 19

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 4 30, at 8 30 — Dr Savatard Epithelioma of the Skin

ROYAL AERONAUTICAL SOCIETY (at Royal United Service Institution), at 5 30 — J D North The Metal Construction of Aeroplanes

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5 30

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6 — Dr. F H. Hayward Something Wrong with Intelligence Tests

CHEMICAL SOCIETY, at 8 — Prof T M Lowry The Polarity of Double Bonds An Extension of the Theories of Lapworth and Robinson.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall) at 8 — Dr Marie Stopes The Ideals and Present Position of Constructive Birth Control (Presidential Address)

FRIDAY, OCTOBER 20

INSTITUTION OF MECHANICAL ENGINEERS, at 6 Dr H S Hele-Shaw Presidential Address

JUNIOR INSTITUTION OF ENGINEERS, at 7 30 — G H Aves Profits from Waste Products

INSTITUTION OF PRODUCTION ENGINEERS (at Royal Automobile Club), at 7 30 — M R Lawrence Presidential Address

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 8 — G A Clarke Record Work in Cloud Photography

PUBLIC LECTURES.

SATURDAY, OCTOBER 14

HORNIMAN MUSEUM (Forest Hill), at 3 30 — H Shaw Flight in all Ages

MONDAY, October 16

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5 — Prof Shattock: The Anatomical Results of Inflammation

CITY OF LONDON Y M C A (186 Aldersgate Street), at 6 —Dr E L. Ash, Mind and Health

TUESDAY, OCTOBER 17

GRESHAM COLLEGE (Basinghall Street), at 6 A R Hinks Astronomy. Succeeding Lectures on October 18, 19, 20

WEDNESDAY, OCTOBER 18

SCHOOL OF ORIENTAL STUDIES, at 5 — J. W Robertson Scott Impressions of the Japanese

UNIVERSITY COLLEGE, at 5 30 — Sir Richard Paget, Bart The Nature and Reproduction of Speech Sounds

THURSDAY, OCTOBER 19

UNIVERSITY COLLEGE, at 4 — Dr T G Pinches Babel and its Gods

CITY OF LONDON Y M C A (186 Aldersgate Street), at 6 —Sir D'Arcy Power Surgery in the City of London

FRIDAY, OCTOBER 20

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5 — Sir Arthur Keith: Hydrocephaly

BEDFORD COLLEGE FOR WOMEN, at 5 30 — F. H Marshall: The Early Civilisation of Ionia.

SATURDAY, OCTOBER 21

HORNIMAN MUSEUM (Forest Hill), at 3 30 — Miss M A Murray: The Nile in the Life and Religion of the Ancient Egyptians.

SATURDAY, OCTOBER 21, 1922.

Sex Economics.

IN his presidential address to the Section of Economics of the British Association at the recent meeting at Hull, Prof F. Y Edgeworth did not hesitate to plunge into the midst of a raging current controversy. "Should men and women receive equal pay for equal work?" were his opening words, and his conclusion is that they should "with some reservations and adjustments"

This conclusion is reached in two stages as follows. In a first approximation Prof Edgeworth relegates dependants to limbo, and shows – we think conclusively – that, granted that freedom of competition for jobs is generally conducive to the best possible distribution of labour, then there is no reason why such competition should be confined to one sex, though it must be a regulated competition, controlled by collective bargaining, in which "the oppressive action of male Trade Unions" is "counteracted by pressure on the part of women acting in concert" The overcrowding of women into those occupations which are open to them, which has resulted from restrictions upon their freedom to compete on equal terms with men in all spheres, is in fact socially uneconomic as well as unfortunate in its effect upon the women's own wages. Prof. Edgeworth goes on to surmise that given substantial freedom of competition we shall find (*a*) occupations almost wholly male, (*b*) occupations into which both men and women enter freely, and (*c*) occupations almost wholly female He submits that the average of weekly earnings in (*a*) will continue to be above the average of weekly earnings in (*c*), while in (*b*), though the rate of pay for a unit of work will be the same for both sexes, the average weekly earnings of the male will continue to be above the average weekly earnings of the female.

Prof. Edgeworth does not offer any particular evidence of these suggestions, which rest upon an assumption that at present, or rather "for a short period in the immediate future," the industrial efficiency of women must be generally inferior to that of men. In point of fact, practically no scientific investigation has yet been made of the relative efficiency of men and women in different occupations. Nor, in view of the close and long-standing restrictions upon the field of women's labour, does the actual distribution of the sexes between different occupations throw much light upon the problem. In quoting the usual examples of telephony, typewriting, textiles, and nursery duties as the female *fortes*, Prof. Edgeworth seems to be allowing convention rather than science to be his guide.

Wise advocates of women's rights will, however,

agree with Prof. Edgeworth when he points out where other things are equal an employer is likely to have a preference for the male owing to the "secondary" drawbacks of the female. Prejudice and restricted opportunities may be responsible for what truth there is in the charge that "a woman is not so useful in the case of a breakdown or a runaway." But it is quite indisputable that the probability of her early marriage is a real drawback to a woman's industrial efficiency. These secondary differences, however, are so difficult to measure accurately that the reduction on their account of the woman's rate per unit of work below that of the man is not a wise or scientific policy. It is better to allow them to make their influence felt upon the occupational distribution of the sexes rather than upon their pay. Of the "tertiary" differences also (of which the illustration given is "the presence and influence of a master—as contrasted with a mistress—in dealing with the bigger boys") the same is true; but there is no evidence to show whether these tertiary differences predominantly favour the male rather than the female.

We now restore the abstracted circumstances of family life. A man normally has, or expects to have, a family to support; a woman normally has not. While the average number of dependants supported by a woman from her earnings has often been greatly underestimated, there is certainly no disputing the general result of Messrs Rowntree and Stuart's figures, which show that this average is much higher for a man than for a woman. The candid will admit that here is the real obstacle to equal pay for equal work; the logical will consider the possibilities of endowment of motherhood as a way out of the difficulty. Prof. Edgeworth summarises the *pros* and *cons* of State endowment of motherhood as follows The proposal is attractive because (1) it would for the first time make competition between the sexes both free and fair; and (2) it would make possible the distribution of resources in such a way as to meet the requirements of the larger family better than is done at present, when the wage paid to a man tends to be adjusted to the presumption that he maintains a family of approximately 4·4 persons, which he quite certainly does not. Against these advantages Prof. Edgeworth sets the following: (1) the scheme is socialistic and bureaucratic, (2) it would almost certainly involve a transference of resources from the rich to the poor and would therefore probably check saving, (3) the effect on the contributor would be "depressing," and there would be (4) a great stimulus to population, and (5) no security for the improvement of the race, but only a prospect of "the ruin of the great middle class to which England owes so much."

We gather that Prof. Edgeworth regards these disadvantages as conclusive. He turns from the State endowment of motherhood to consider one or two other suggestions, the principal of which is his own proposal that the members of Trade Unions might themselves contribute a quota of their earnings to a fund to be distributed among the wives of members in accordance with the size of their families. In regard to this proposal Prof. Edgeworth does not commit himself beyond the canny statement that it would be much less open to objections than the endowment of motherhood by the State.

Prof. Edgeworth's address is open to little criticism from those who grant his premises. All will applaud his careful analysis of his subject. It is, however, at least open to question whether his whole treatment of the matter does not suffer immensely from the limitations which he has imposed upon himself. In his first approximation the assumption that "regulated competition" (a very vague concept) is a royal road to ideal distribution is open to serious criticism. Secondly, any discussion of endowment of motherhood which assumes outright that (*a*) transferences of resources from rich to poor would be entailed, and that (*b*) these are objectionable, rests on questionable ground. To the present writer this double assumption appears fatal to Prof. Edgeworth's conclusions regarding the right relation of the basis of payment to family circumstances.

BARBARA WOOTTON.

Fishing and Fishing Lore.

Fishing from the Earliest Times. By W. Radcliffe. Pp. xvii+478. (London: J. Murray, 1921.) 28*s*. net.

THE literature connected with fishing is already so extensive that a new volume is liable to be subjected to scrutiny to see whether it can justify its birth by furnishing new matter or new ideas. As the more obvious gaps in the literature of the subject become fewer, the tests will necessarily become more searching. Mr. Radcliffe's book, fortunately, can claim a definite *raison d'être,* and may receive an enthusiastic welcome as filling a decided gap, one which it is curious should have so long remained void. His aim has been to provide a history of the fishing art and craft from the earliest times down to about A.D. 500. The title scarcely does justice to the contents of this versatile volume, which is far from being restricted to the consideration of actual fishing practices. These, indeed, probably occupy but a third of the book. The remainder is very largely concerned with what may be classed as the folk-lore associated with fish, fishing, fishermen, and fish-consumers, and with other details

which are by-products of the industry. Mr. Radcliffe has been at great pains to bring together a great mass of material which he has collated and coaxed into a very readable form. The illustrations are both good and numerous. The result is an important work which is both entertaining reading, and of considerable value as a comprehensive book of reference. In the main, it consists of classified quotations which are analysed and evaluated by the author. One would gather that the author has thoroughly enjoyed his self-imposed task. He revels in argument, and while now and then he may, perhaps, be suspected of "special pleading," his interpretations of doubtful or obscure passages are always interesting and suggestive, even when he fails to be entirely convincing.

The introduction extends over sixty pages and deals with a number of points of general interest and with early prehistoric fishing. For our knowledge of fishing practices during the Stone and Bronze Ages we are dependent upon evidence which is, unfortunately, meagre in amount, and requires much speculation for the completion of the picture. Mr. Radcliffe has not made an intensive study of fishing as practised by *recent* Stone-age peoples, and he makes but slight use of the evidence which they can afford, valuable though it may be for the light which it can throw upon the archæological record. Ethnological data must be brought to bear upon archæological research if an adequate diagnosis of early customs and appliances is to be achieved. A comprehensive work dealing with fishing pursuits and methods among the recent "unrisen" peoples, the progress of whose more or less primitive culture has been arrested or retarded at various stages of advancement, still remains to be written. When such a work, based upon comparative study, is available, archæological commentarists will find a valuable ally which will assist materially in their interpretations of ancient data.

The present volume would have gained by a wider reference to evidence derived from ethnological sources, and some of the problems with which Mr. Radcliffe deals so interestingly might have been more convincingly attacked or solved. Mr. Radcliffe takes especial delight in tracing the earliest references to various fishing-appliances [See Figs. 1 and 2 here reproduced by the courtesy of the publishers.] To Martial he assigns the first mention of the jointed rod (*crescens harundo*), and of fishing with a fly; but to Ælian the first definite reference to the use of an *artificial* fly. In dealing with the latter, he appears to be convinced that the artificial fly of those days was an imitation, as close as possible, of a *natural* fly; but this view does not seem to be borne out by Ælian's description, which rather suggests the reverse, *i.e.* a type of lure which was a novelty to the fish, which were attracted by its unusual gaudiness. Aristotle is given credit as the first "scale-reader" in estimating the age of fishes. There seems to be a zoological confusion when Mr. Radcliffe uses evidence from two passages, one of which refers to the *scales* of fish which afforded an indication of age, while the other relates to the growth indications upon the *shell* of a Murex (a mollusc). But zoological differentiation is

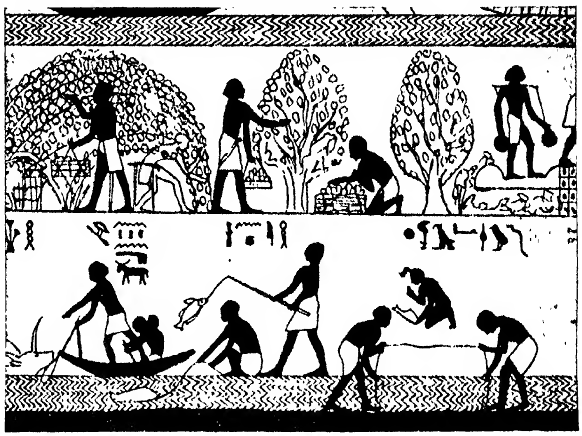

FIG. 1.—The earliest representation of angling, c. 2000 B.C. From "Fishing from the Earliest Times."

scarcely Mr Radcliffe's strong point, and he apparently is convinced that dolphins are to be classed with the fishes (pp. 91, 92, 95, 165, 450, etc.), and this in spite of the fact that Aristotle, whom he quotes, recognised essential differences between fish and cetacean mammals. The plate opposite p. 180 is described as illustrating a "pattern of Torpedo fish"; but the three fishes represented clearly belong to three distinct varieties, all of them *bony* fishes, whereas the Torpedo fish (a kind of ray) belongs to the group of *cartilaginous* fishes. Again, on p. 414, he includes shell-fish among the fishes prohibited by Moses, without any covering comment. These "termino-zoological inexactitudes" tend somewhat to obscure the scientific status of the book.

A time-honoured controversy is revived and reviewed in detail in chapter 2, where the author deals with the various interpretations of the function of the ox-horn (κέρας βοὸς ἀγραύλοιο) referred to in the "Odyssey"

(xii. 251 ff.) and "Iliad" (xxiv. 80 ff.) in connexion with similes derived from fishing processes. The very varied theories are quoted and evaluated with skill, and the author himself inclines toward the suggestion of C. E. Haskins, namely, that the *κέρας* was an artificial bait of horn. This controversy has been carried on in the pages of the *Times* Literary Supplement, in reviews of the book, and in letters arising therefrom. The whole discussion, however, leaves one unconvinced and still wondering. Since the controversy still remains "fluid," I am tempted to offer yet another possible solution, to take its chance with those previously offered. Line-fishers on the coast of Western Ireland employ a very simple and ingenious contrivance to overcome the difficulty which arises from their hooks becoming entangled in seaweed, when fishing is pursued in rock-studded waters. It is desired to sink the baited hook below the level of the weed layer, and the problem is to pass it through the tangled and entangling mass. To achieve this, at a short distance above the hook there is attached to the line a crab's claw, which serves as a stop. Still farther up the line a weight (or sinker) of lead or stone is fastened, and between the stop and the weight an empty carapace of a crab is loosely threaded upon the line, so that it can slide along the latter between the sinker and the stop. When the line is cast out by the fisherman, the weight descends first, dragging after it the line; the water-resistance causes the bell-like carapace to slip along the line as far as the stop, so that it covers and protects the baited hook as it is carried downward through the weed stratum. Since the carapace is very light it probably floats away from and uncovers the bait when the line becomes stationary at the desired depth. Similarly, as the line is drawn in the resistance of the water drives the bell down over the hook and again protects it on the upward journey. Now, substitute a selected bell-shaped ox-horn for the crab's carapace and a slightly more efficient form of this apparatus is devised, which should serve the same purpose admirably.

FIG. 2.—The happy fisherman, attributed to the artist Chachrylion. From "Fishing from the Earliest Times."

The merit, if any, of my suggestion is derived from the following facts, (1) that the apparatus which affords a seeming clue to the function of the *κέρας* is an actual one still in practical use locally, and is very possibly a survival from an ancient type formerly far more widely employed; (2) that the much-debated "resounding splash" (cf. *στονάχησε δὲ λίμνη* in the Iliad passage) is plausible as a description of the effect produced by casting such an apparatus into the sea; (3) that it is consistent with fishing from a headland on a rocky and weedy coast such as, I believe, is characteristic of southern Italy and of the region lying between Samos and Imbros, the areas to which Homer's two similes are applied; (4) that it conforms with the picturesque description of the dive of Iris when she "sped to the bottom like a weight of lead, that mounted on the horn of a field-ox goeth down, bearing death to the ravening fishes"; (5) that the *κέρας βοὸς ἀγραύλοιο* which some commentators aver must imply the *whole* horn, and not merely an object made of horn, would, for the purpose I have suggested, have been practically entire, so that the hook could be withdrawn into its protecting cavity. A small hole drilled in the apex (through which to pass the line) would be the only essential modification required. The expression "mounted *on* the horn" alone offers some difficulty; "near" or "with" instead of "on" would certainly have added weight to my suggestion.

The problems suggested by or dealt with in this book are numerous, and Greek, Roman, Egyptian, Assyrian, Jewish, and Chinese fishing methods and fishing lore

all receive detailed and careful treatment. The author has brought to bear upon his task the experience of a practical and enthusiastic angler, and the zest of a keen student. While he realises the more serious aspects of his theme, he has dealt kindly by the general reader and writes in a light-hearted, attractive, and unpedantic manner. In this way he should be instrumental in developing a wider interest in and stimulating further research into the history of one of the oldest industries, and has given us the story of progress from a humble and despised craft to a popular and respected art.

HENRY BALFOUR.

The Metallurgy of Iron and Steel.

(1) *Engineering Steels.* By Dr L. Aitchison. (Reconstructive Technical Series.) Pp xxxi+348+48 plates. (London: Macdonald and Evans, 1921.) 25s. net.

(2) *The Case-Hardening of Steel: An Illustrated Exposition of the Changes in Structure and Properties induced in Steels by Cementation and Allied Processes.* By H. Brearley. Second edition. Pp. xi+207. (London: Longmans, Green and Co., 1921.) 16s. net.

(3) *Iron-Founding.* By B. Whiteley. (Pitman's Common Commodities and Industries.) Pp. 131. (London: Sir I. Pitman and Sons, Ltd., 1921.) 3s. net.

(1) THE advance of metallurgy in recent years has placed at the disposal of the engineer a wide range of new materials, including alloy steels which so far surpass the older, plain carbon steels in strength and toughness as to constitute a new class of metals. In the face of such diversity the engineer finds difficulty in selecting the most suitable material for a given purpose, and is not in a position to judge between the products offered by manufacturers, or recommended by specialists. There are in existence many excellent memoirs and a few books on the subject, but they are written for the metallurgist, and assume a technical knowledge that lies outside the usual field of study of the engineer. It is highly desirable that the user of a metal should understand its properties as well as the maker, and Dr. Aitchison has made the attempt, largely successful, to describe the steels now available for engineering purposes, without assuming a knowledge of chemistry or metallurgy.

The title of Dr. Aitchison's book must be interpreted in a rather restricted sense. The engineer is interested in such steels as those used for ship and boiler plates, rails, and girders, but he will find little in reference to them, the work being mainly concerned with steels required by the automobile and aircraft industries. It is these steels of high tensile strength, often required to withstand severe alternating stresses, that present the greatest difficulties of specification and testing, and it is very necessary that the information regarding them should be collected and placed clearly before the engineering user, as has been done here. There is a very brief account of methods of manufacture, sufficing to indicate the distinction between various classes of steel, and a discussion of ingot structure, so far as is required to explain the possible sources of defects in forgings.

It is probably on account of the limitation mentioned above that only piping steel is described, and the subject of blowholes is not mentioned. Steel castings are omitted entirely, although of great interest to the engineer who uses high tensile steel forgings for other parts of his machine. The desire to avoid chemical and metallurgical difficulties leads to a somewhat excessive simplification of the chapter on heat treatment, and the author's account of hardening and his explanation of the critical points is rather misleading, although not likely to cause misunderstanding of the practical instructions. It should be said that the style is easy and readable throughout.

The subject of mechanical testing is well treated, proper attention being given to the determination of the fatigue range and its relation to the other measurements usually made in the testing laboratory. Much of the experimental material in this chapter is taken from the author's reports to the Aeronautical Research Committee. His conclusions may not always be accepted, but the importance of the subject is rightly emphasised, and the descriptions of fatigue tests and the short accounts of other special methods of testing are valuable. There are very few references to original sources, but a full bibliography of papers relating to the determination of hardness is given.

The alloy steels are considered in detail, the properties of each steel, as modified by different heat treatments, being shown by means of diagrams similar to those published by the Automobile Steel Research Committee; these diagrams provide a useful guide to the characteristics of the various classes of steels. Case-hardening and cold-working are other subjects dealt with.

The book is very well printed and illustrated, many of the best plates being selected from Mr. Brearley's works, while others show special types of testing machines. The whole subject of the relative value of tests for steels of this class is in a state of flux, and an authoritative statement is not yet to be expected, but Dr. Aitchison has made a good beginning, and his efforts will be welcomed by engineers.

(2) The first edition of Mr. Brearley's book on case-hardening was published in 1914, and it is an indication

of its trustworthy character that scarcely any statement contained in it has had to be withdrawn in the preparation of the new edition The subject-matter has been widened by the inclusion of further particulars concerning alloy steels of the class frequently employed in automobile construction, and by the addition of sections on specifications, in regard to which the author expresses decided opinions, based on a wide experience. The treatise is of more general interest to the metallurgist than might be assumed from its title, since the description of the materials and processes of case-hardening and of the defects that may occur in case-hardened objects, involves the discussion of many other points of importance in the treatment and use of steel. On all these subjects, the advice given is sound and admirably clear in its expression. Only two minor points have been noted for criticism There is no mention of nichrome carburising boxes, although these are now frequently used, and justify by their long life the increased cost Plating with copper, as a means of local protection against carburisation, is still spoken of as unsatisfactory, although it has been practised with great success in the construction of aero-engine parts.

(3) The third work on our list is an elementary handbook on iron-founding It contains a simple description of foundry methods, and the illustrations include a series of photographs of the mould for a gas-engine cylinder at various stages Moulding is considered much more fully than melting, and the book is well adapted to give a general idea of the processes used in preparing moulds, and of the organisation of a foundry. The theoretical side is weak, and some very erroneous statements as to fuel and thermochemistry would have been better omitted The printing and illustrations are good

C. H. DESCH.

The Snakes of Ceylon.

Ophidia Taprobanica, or The Snakes of Ceylon. By Col. Frank Wall Pp xxii+581+1 map. (Colombo: Colombo Museum, 1921)

A GOOD deal has been written on the subject of the snakes of Ceylon. Thus Gunther's "Reptiles of British India" (1864), and Boulenger's "Fauna of British India—Reptiles and Batrachians" (1890), both include descriptions, and in the case of the former work remarks on the habits of many of the snakes inhabiting Ceylon. There is also the "Snakes of Ceylon" by Abercromby, a small popular treatise which appeared in 1910. Except for the last-named work, which is very incomplete, there is, however, no book which deals solely with the snakes of Ceylon, apart from those inhabiting India, and Col. Wall, an enthusiastic naturalist and specialist on Indian snakes, in producing the volume under review has succeeded in filling a long-felt want.

The author in his work gives an account of the marine snakes which may be met with around the shores, as well as the terrestrial forms A full description is given of every snake, and the determination of the genera and species is often facilitated by useful, if somewhat unscientific, keys Except when dealing with the sea-snakes, Col. Wall has in most cases adopted the nomenclature used in Boulenger's Catalogue of the British Museum. Sometimes the generic and specific names have been altered It is impossible without going thoroughly into the various contested points to say whether the author is in every case justified in departing from Boulenger's classification, although he occasionally appears to have good reasons for so doing We are not, however, always inspired with confidence in Col Wall's judgment. Thus "until I am satisfied of their specific unity I prefer to regard them as distinct species" is the dogmatic reason he gives when advocating specific distinction for certain forms of Kraits, held by Boulenger, in spite of their distinctive coloration, to be only geographical varieties of the same species.

A feature of the book is the very full account given of the habits of the snakes. The author has had practical experience of the reptiles in their native haunts, and his descriptions of their feeding and breeding habits add greatly to the value of the work There are also some interesting remarks on the subject of distribution. Many snakes inhabiting upland regions have a very restricted habitat, neither ascending nor descending beyond certain limits The elevated ranges and peaks, where the lower slopes merge into the low country, are just as effectually isolated as if they were surrounded by the sea.

Much space is devoted to the subject of snake-bite, for the benefit of the medical practitioner, and a number of illustrative cases from the records of various doctors are given.

E. G. B.

Japanese Social and Economic Life.

The Foundations of Japan: Notes made during Journeys of 6000 Miles in the Rural Districts as a Basis for a Sounder Knowledge of the Japanese People By J W. Robertson Scott. Pp. xxv+446+plates. (London J. Murray, 1922) 24s. net.

THIS is an eminently readable book, giving not only the familiar glimpses into superficial Japanese life, but also treating of the economic life of

the nation in a really profound manner. The author spent four and a half years travelling through the country, studying the habits and thoughts of the men and women of the countryside, who were trained under rural schoolmasters and village elders and are living their life under the potent sway of long-established tradition. The modern industrial developments of factory life are also depicted with a sure hand, and where there is much to praise there is also much to condemn. For example, the conditions under which silk-factory girls work are little short of slavery, and would be impossible in English-speaking countries. On these and other deeper aspects of Japanese life the author evidently speaks with knowledge. With real sympathy and honesty he describes the present-day sociological conditions which rule among the great majority of Japanese. As he himself says, he went to Japan to see the countrymen

"The Japanese whom most of the world knows are townified, sometimes Americanised or Europeanised, and, as often as not, elaborately educated. They are frequently remarkable men They stand for a great deal in modern Japan But their untownified countrymen . . . What is their health of mind and body? By what social and moral principles are they swayed? To what extent are they adequate to the demand that is made and is likely to be made upon them?"

Such are some of the questions which Mr Scott sets himself to answer This he does by describing his wanderings in various provinces, touching upon all kinds of Japanese customs as they come before him The result is in many cases a curious mosaic of random thoughts, greatly satisfying to one who has lived in Japan, but probably not a little confusing to one who has never been there and is reading for enlightenment. In other chapters, however, there is a sustained and serious discussion of some broad aspect of Japanese life In all cases the author writes with a freshness and accuracy which bespeak a full knowledge and a discriminating judgment

Dealing as it does with the facts at the basis of human life, the book is aptly called the "Foundations of Japan" From this point of view the book is a real addition to ethnological literature, and is worthy of commendation in the pages of NATURE For the more serious student of industrial economy there are some interesting appendices with instructive statistics; and well-chosen drawings and photographs elucidate many of the questions discussed Among the subjects treated at considerable length are the cultivation of rice, the whole process of sericulture, the problem of labour, and the education of boys and girls In conclusion it may be said that Mr Scott has the gift of a true teller of stories, many of which show forth in a graphic way some characteristic traits of our Eastern Allies.

Hull and the East Riding.

Handbook to Hull and the East Riding of Yorkshire: Prepared for the Members of the British Association for the Advancement of Science on the Occasion of their Visit to Hull, in September 1922 Edited by T. Sheppard Pp viii + 532 (London and Hull A. Brown and Sons, Ltd 1922) 5s

THE ideal handbook in connexion with the annual visits of the British Association has yet to be written, but it would be unfair if we withheld the full meed to the editor and sub-committee who have produced this interesting publication It approaches nearer to our ideal than that issued at any previous meeting, so far as possible technicalities have been avoided, for the work is not intended for the expert, who already knows the special works and articles relating to the different subjects treated of It is essentially a guide for the average member who wishes to learn something of the history, archæology, antiquities, folk-lore, geology, natural history, and economics of the town and district in which the parliament of science has recently been held.

After a brief account of the evolution and growth of Hull, we pass on to short accounts of its past history and antiquity, its rise and progress, places of interest, Hull coins and tokens, its charters, etc The various prehistoric remains of East Yorkshire are briefly described and illustrated, and interesting chapters are devoted to the Romans, Anglo-Saxons, and Danes in this division of the county The Rev Canon A N Cooper contributes a well-illustrated chapter on East Riding churches, and Mr. John Nicholson one on East Riding place-names There are further sections treating of the charities, engineering and shipbuilding, education, agriculture in the East Riding, while the geology and lost towns of the Humber receive very full treatment at the hands of the editor.

Nearly three hundred pages are devoted to the description of the fauna and flora, and in spite of the fact that some of the writers have not been able to depart from the useless local list method of treatment, the various contributors have handled their sections most ably. An outstanding feature is Mr. John W. Taylor's excellent account of the land and freshwater mollusca. The weakest section is undoubtedly that on the crustacea, which is unfortunate, as much good work has been done on the non-marine forms

Apart from its value and usefulness to the visitor to Hull, this work will fulfil a double service if it serves

to show the citizens of Hull the many points of interest their city possesses, and of which they are the trustees.

The wealth of illustrations considerably adds to the interest of this work. Future compilers of the British Association local handbook will do well to study carefully the Hull model. W. E. C.

Our Bookshelf.

The Biology of the Seashore. By F. W. Flattely and C. L. Walton. Pp. xvi+336+16 plates. (London: Sidgwick and Jackson, Ltd., 1922.) 16s. net.

The study of zoology from the ecological standpoint has made rapid strides in America under the energetic leadership of Dr. Adams and Dr. Shelford, and there has been a steady output of text-books and popular books on Nature study written from this point of view. In this country, zoological ecology has received very little attention, and we welcome, therefore, it only on these grounds, this excellent work on the biology of the seashore. As the authors point out, their book is not intended to supersede but to supplement previous works which have been written on classificatory and morphological lines. In fact, they demand a previous knowledge of classification and external morphology in those who use their work. Given this the authors have directed special attention to functional biology and to the adaptations which organisms present to marine life in all its phases.

The book is an exhaustive summary of the known facts of marine biology from the ecological point of view, and reveals a wide knowledge of the literature of the subject. The illustrations are good and adequate, and the advice given on the methods of ecological research should be most useful to students. The authors, however, have not been content merely to summarise known facts. The book bristles with suggestions for research and further inquiry, and in this respect is most stimulating. It should be in the hands of all students of marine biology. With its help more real knowledge of life in the sea will be obtained than from any other text-book we know. It is not enough to know the mere population of the sea; some knowledge of the laws governing life there, and of the actions and interactions of organism and environment is vastly more interesting and stimulating, and the work under notice supplies the right kind of guidance in this inspiring field of study.

Catalogue of the Books, Manuscripts, Maps, and Drawings in the British Museum (Natural History). Vol. 6. Supplement: A–I. Pp. iv+511+48. (London: British Museum (Natural History), 1922.) 2l. 15s.

The Library of the British Museum of Natural History is probably one of the most complete, and certainly one of the most important, libraries of works on natural history in the world. The publication of a catalogue of its contents has been of immense service to scientific workers, who find in it a valuable guide to the literature of their subject and a wealth of bibliographical detail which is of the greatest value in settling vexed questions of priority and ensuring accuracy of reference. The first half of the supplement to the main catalogue has now been issued and serves to give some idea of the natural growth of this splendid library. Like the preceding volumes, it has been prepared by Mr. B. B. Woodward with the same meticulous care and accuracy, and includes as before the results of much bibliographical research by the author and Mr. C. D. Sherborn. The 48 pages of "Addenda and Corrigenda" to the main catalogue consist almost entirely of additional bibliographical information which has accumulated since the catalogue was published.

The expenditure of public money on the publication of a catalogue of this kind is more than justified by its extreme value and usefulness, though it is a pity that so valuable a work as this supplement should have been sent out in a paper cover. For its own value and for the sake of uniformity it is worth a binding similar to its predecessors. Scientific workers are grateful to Mr. Woodward and to the trustees of the British Museum for having made the resources of their library known in this readily accessible form.

Obras completas y correspondencia cientifica de Florentino Ameghino. Volumen 3. La Antiguedad del Hombre en el Plata. Dirigida por Alfredo J. Torcelli. Pp. 821. (La Plata: Taller de Impresiones Oficiales, 1915.) n.p.

The third volume of the handsome collected edition of the late Florentino Ameghino's geological and palæontological works now being issued by the government of the province of Buenos Aires, is a reprint of his treatise on the antiquity of man in La Plata originally published in 1880. Francisco Moreno had then just founded the Anthropological and Archæological Museum at Buenos Aires (afterwards removed to La Plata), and Ameghino himself was studying with Henri Gervais in Paris, where he exhibited part of his collection at the Universal Exposition. The author was thus well furnished with materials, and had unusual opportunities of making himself acquainted with the latest advances in the subject of the antiquity of man. While describing the results of his own researches, he therefore took the opportunity of making many references to European and North American work which were illuminating. His volume is a most exhaustive discussion of the remains of the handiwork of prehistoric man discovered in Argentina, illustrated by twenty-five large plates. Of the skeleton of man himself no important fragments had at that time been found. The geological observations are particularly valuable and interesting, and Ameghino seems to make it quite clear for the first time that the man of the pampas was a contemporary of the extinct glyptodonts or giant armadillos, and actually used their large bony carapaces as roofs for his lowly habitations. Although naturally out-of-date, the whole treatise is a valuable record of facts and observations, in which the reprint will stimulate renewed interest. A. S. W.

Le Pôle Sud: Histoire des voyages antarctiques. Par J. Rouch. Pp. 249. (Paris: Ernest Flammarion, 1921.) 7 francs net.

M. Rouch was one of the officers of the *Pourquoi Pas?* in Dr. Charcot's second Antarctic expedition, and familiarity with the conditions of navigation and the privations of wintering in the Far South has given him

a great advantage in dealing with the history of exploration in the South Polar regions. With the space at his disposal no one could have done better than M. Rouch in setting forth with equal detail all the outstanding Antarctic voyages from that of Cook in the *Resolution* to that of Shackleton in the *Endurance*. Except for a very few slips in the spelling of names (*Thun* instead of *Chun* on the *Valdivia* is the only serious one) the accuracy of the work is quite remarkable, and the facts regarding the various expeditions have obviously been selected from the original narratives.

The style is lively and sympathetic but concise and sailorly. M. Rouch holds all explorers as his brothers and there is a delightful air of *cameraderie* in his treatment of the aspirations and achievements of British, French, Russian, American, Swedish, Norwegian, and German explorers. It is refreshing to find this fine French sailor giving credit impartially to his German rivals and his French colleagues, and with an almost British self-criticism touching more frankly on the little shortcomings of his fellow-countrymen than on those of foreigners.

Perhaps the author's imagination has assisted a little in describing the details of Scott's last expedition, but if he here allows dramatic truth to prevail over verbal accuracy it is in excess of sympathy.

The numerous illustrations are excellent as showing Antarctic conditions, but they obviously refer only to the author's own section of the region. H. R. M.

Mineral Land Surveying. By Dr. J. Underhill. Third edition, revised. Pp. viii+237+3 plates. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 17s. 6d. net.

DR. UNDERHILL'S book describes the methods in use for the survey of the mineral lands in the western portion of the United States. It should certainly be in the possession of all surveyors who intend to proceed there, but only the first three chapters are likely to be of much service to mine surveyors in England. In chapter 1, on direct solar observation, the method of obtaining the true meridian by single observations on the sun is clearly and fully explained, with the aid of several worked examples, after the derivation of the formula employed has been given. The method of obtaining latitude by solar observation is also briefly described. Chapter 2 describes the Shattuck Solar Attachment, the Burt Solar Attachment, and the Berger and Saegmuller Solars and their use for finding true meridian and latitude. Of these, the Shattuck Solar Attachment appears to find most favour with the author, who states that he has obtained perfect checks on this instrument by direct observation of the sun. Chapter 3 is a useful account of traversing and measurements, including stadia measurements. Other chapters deal with location surveys, including calculation of areas by the double meridian distance method, patent surveys, patent field notes, Land Office and Records, and the examination for commissions as United States Mineral Surveyor with typical questions and solutions. The appendix includes extracts from the Manual of Instructions for the Survey of the Mineral Lands of the United States.

L'Océanographie. Par Prof. J. Thoulet. (*Science et Civilisation: Collection d'exposés synthétiques du savoir humain.*) Pp. ix+287. (Paris: Gauthier-Villars et Cie, 1922.) 9 francs.

THIS book is one of a series which offers a general account of modern scientific research in its relations to civilisation: it is written in a pleasant, continuous manner and, on the whole, is a very good exposition of the main results of physical oceanography. It follows the line of treatment which appears now to have become classical since the publication of Krummel's big book in 1907–11: an account of the bottom of the ocean and its deposits, the physics and chemistry of sea water, waves and tides, and the formation of ice. The ocean in its relation to life and the development of the foreshore and coast-line are scarcely touched. The theory of the tides is dealt with very slightly, and the statement is made that all tidal problems have been elucidated by Airy's "théorie des ondulations": quite lately, of course, the dynamical theory of the tides has been almost transformed. There is no account of the methods of prediction.

In such a work as this figures and charts are indispensable, yet the book under review only contains eight text-figures and these are rather difficult diagrams. It can be read with advantage and by the non-professional reader only with constant reference to a good atlas of physical geography, and there is no such work in existence which includes all the recent investigations of marine currents and drifts. J. J.

The Misuse of Mind: A Study of Bergson's Attack on Intellectualism. By Karin Stephen. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. 107. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1922.) 6s. 6d. net.

THIS important study of Bergson's philosophy is not an attempt to epitomise or expound the principle, the method, or the particular content. It concentrates on an attempt to understand what is generally rejected as unintelligible—the attack on intellectualism. In Bergson's view the tradition of philosophy is all wrong and must be broken with; philosophical knowledge can be obtained only by "a reversal of the usual work of the intellect." The author gives us in three chapters first a criticism of "explanation," then a criticism of "fact," both with reference to Bergson's theory of change, and in a final chapter shows how light is thrown on the problem by his theory of the relation of matter to memory.

Les Sciences et le Pluralisme. Par J.-H. Rosny, aîné. (Nouvelle Collection Scientifique.) Pp. iv+219. (Paris: Félix Alcan, 1922.) 8 francs net.

M. ROSNY'S thesis is that "pour retrouver l'uniforme nous sommes contraints de nous rabattre sur des substances ou des énergies hypothétiques. En fin de compte, l'homogène que nous trouvons est subi ou créé par le moi, mais non strictement *donné par les choses*." The volume contains a lucid discussion of the most recent theories in mathematics and physics.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mersenne's Numbers.

IN my presidential address to Section A of the British Association, reprinted in NATURE (September 16), I stated that 137 was the least value of n for which the prime or composite character of $2^n - 1$ was still undecided. Mr. W. W. Rouse Ball has pointed out to me that this is incorrect, as $2^{137} - 1$ has been shown to be composite by M. A. Gérardin (*Comptes rendus du Congrès des Sociétés Savantes*, 1920, pp. 53-55). The result is quoted in *The American Mathematical Monthly*, vol. 28, 1921, p. 380. The number 139 should therefore be substituted for 137 wherever it occurs in my address.

The authorities on which I relied were Prof. L. E. Dickson's "History of the Theory of Numbers" (vol. 1, Washington, 1919) and the seventh edition of Mr. Rouse Ball's "Mathematical Recreations" (1917, now superseded by the tenth). My quotation from Mr. Rouse Ball was taken, as I stated, from a pamphlet written thirty years ago, and is, of course, not to be interpreted as an expression of his present view. G. H. HARDY.

New College, Oxford, October 4.

Animal Mechanism.

THE notion that the legs of animals behave as pendulums is ascribed to the brothers Weber. I can find no indication that the notion was more than a general one, and, in the general sense, when pointed out, it is obvious to a student of dynamics, for legs have inertia and weight and dynamics is reasonably near to the truth.

A better view may arise from the supposition that animals may be regarded as dynamical systems with many natural modes and frequencies, and that animals adapt their methods of locomotion and other actions to suit these fundamental characteristics. As examples, we have the lounging gait of very tall men and the apparently energetic step of short men. The tripping, half running step of women and children is also in point. Apart from mere legs the moment of inertia about the feet must be important, as may be seen in the stately carriage of quite short women in the East when carrying water vessels on the head. Sir George Greenhill has given several examples of this in his notes on dynamics, among them being interesting examples of the carrying of soldiers' kit.

A further point of interest arises in regarding legs a little closely, for they are not simple but multiple pendulums with more than one natural mode. When a horse or man is walking the leg appears to vibrate in the slowest mode of the pendulum and the joints are or appear to be on one side of the vertical. In the running gait, however, the thigh points forward while the lower parts point backwards. Probably the "reason" why a horse's forelegs are more flexible than the hind legs is to make him nimble in balance and steering; a horse could not stumble with his stiff hind legs.

The dynamics of locomotion is of interest to the student of engine balancing, for in the natural gaits of man and horse there is a utilisation of balancing principles. In man the right leg moves forward while the right arm moves backward, in the horse the right legs are always moving in opposition and similarly the left legs, of course. This holds for the walk, the trot, and the gallop, all natural modes. In the amble, an artificial stride due to the trainer, the legs on either side are in phase and an ungainly motion results, though it is comfortable for the rider. This amble stride is natural to the giraffe, but the latter has a long neck to give it poise. The balancing view of animal locomotion may be realised at once by any one who will try to run with stiff arms or will try to walk with his arms tucked up in the running posture. The runner is compelled by dynamics to move his legs in a quicker mode than when walking. His arms are so jointed that he cannot alter their type of vibration, and he is therefore compelled to reduce their inertia in order that they may oscillate in time with his legs. The balance from the engineer's point of view is imperfect, and thus stresses are imposed in the trunk. Hence sprinters are well-bodied men and horses need girth for speed. As a final example of these facts, let any one try to run to the station with a heavy suit-case in his hand. Porters usually carry such things on their shoulders and stride rather slowly.

There is a further point of interest in connexion with the viscera. If dynamics is true, the various internal organs have inertia and their attachments have elasticity; thus they must possess natural frequencies. This being so, they must be subject more or less to the phenomena of resonance. Is sea-sickness, subjective agencies apart, to be explained in this way? Some people before embarking have a copious meal, others pin their faith and hope to a single bottle of stout, while yet others proceed fasting. Is this a phase of dynamical tuning? In 1914 I read a short paper on the dynamics of the human foot at the British Medical Association's summer meeting. The outcome of the discussion was that tonicity was more potent than mechanics, or, in other words, living tissue may vary in its properties on account of tone or debility to a degree which will exceed the influence of configuration. The contention would be that while astringents or food may alter the effects of a sea voyage, the action is due to dynamical effects; the inertia of the stomach or the stiffness of its suspension is varied—opiates and such like are here excluded.

A medical writer of some eminence recently advocated walking because "Nature has ordained that the finest exercise of all is that which she bestows." While this is reminiscent of Heine's "Harzreise," the greenness of grass and the length of a donkey's ears, there is in it matter for reflection. Motor car designers, led by Dr. Lanchester, have found that the most comfortable predominant natural frequency of a motor car is between 80 and 100 per minute; it is a curious coincidence that this is also the frequency of the ordinary walking step. Has the human system, enforced by dynamics to walk in a certain rhythm, acquired an internal system and a nervous organisation to meet this rhythm? It is worthy of note that in certain cars several dogs and children have been actually and violently sick and in other cars sprung to vibrate with a different natural period they are immune. Shall we, disagreeing with Shylock, say, "It is not their humour, but their natural frequency"?

Vegetable Rennet.

I HAVE been endeavouring to make a list of plants—leaves, flowers, seeds, etc.—used in various countries for coagulating milk in place of rennet, obtained from the stomachs of young animals, and I shall be glad to learn of any additions that might be made to the following list:—*Galium verum, Withania coagulans, Ficus Carica, Cynara cardunculus, Cynara scolymus, Carduus nutans, Cnicus benedictus, Drosera peltata, Datura Stramonium, Pisum sativum, Lupinus hirsutus, Ricinus hirsutus, Pinguicula vulgaris, Leucas cephalotes, Crotalaria Burhia, Rhazya stricta* and *Streblus asper*.

With regard to some of the plants named above, I would note that the references are not very clear as to their use for milk coagulation. Any information as to plants used in former days or at the present time would be welcome and useful. A Hindu, also an orthodox Jew, cannot touch, I understand, a milk product that has been coagulated by rennet obtained from a calf's stomach, and must therefore use a vegetable coagulant, and I believe that there are other races in other parts of the world which use vegetable coagulants. So far as I am aware, an approximately complete list of plants used in various parts of the world for coagulating milk does not exist, and where a reference is found, details given are scanty as to part of plant used, its preparation, and method of use.

A Question of Nomenclature.

IN his notice of Mr. S. Q. Hayes's "Switching Equipment for Power Control" in NATURE of September 16, p. 374, your reviewer, commenting on current Americanese, says: "Electrical engineers talked about 'omnibus bars' thirty years ago, it then became 'bus bars,' and now apparently it has become 'busses.'" Webster, who may be considered as an authority on the language of that great nation, defines a buss as "a kiss; a rude or playful kiss; a smack," and quotes Herrick to the effect that

Kissing and bussing differ both in this,
We buss our wantons, but our wives we kiss.

So that although in both "bus bars" and "busses" there is intimate contact and at times electricity passes, it can scarcely be said that the two terms are synonymous. Nor can it be said that the introduction of such terms into electrical engineering is to be commended.

F. H. MASTERS.

Capillarity.

IN a letter on capillarity in NATURE for September 16, p. 377, Mr. Wilson Taylor shows how difficult it is to account on physical grounds for the phenomena exhibited by liquid films.

It may not be out of place in the circumstances to refer to Irving Langmuir's views on this subject, given by him in a paper on "The Constitution and Fundamental Properties of Solids and Liquids. II. Liquids" (Am. Chem. Soc., vol. xxxix., September 1917, p. 1852). Langmuir cites a few of the cases in which the forces between the molecules have been considered to be radial forces which vary solely as a function of the distance between molecules. In all these cases the investigator has considered the phenomena to be physical in nature. He then goes on to remark: "The chemist, on the other hand, in studying the properties of matter, usually employs totally different methods. He is often most interested in the qualitative aspects of the problem, and the quantitative relationships are usually limited to those deducible from the law of multiple combining proportions, the law of mass action, or the principles of thermodynamics. When the chemist does consider the forces acting between atoms and molecules, he does not look upon these as forces of attraction between the centres of the molecules, but he thinks rather of the specific nature of the atoms forming the molecules and the manner in which these atoms are already combined with each other. He thinks of molecules as complex structures, the different portions of which can act entirely differently towards any given reagent. Furthermore, he considers that the forces involved in chemical changes have a range of action which is usually much less than the diameter of a molecule, and perhaps even less than that of an atom."

What has been termed the Classical Theory of surface forces has proved useful in its day, but it unfortunately ignores *chemical affinity*.

Lead and Animal Life.

DR. GARRETT'S communication in NATURE of September 16, p. 380, on the effect of a lead salt on Lepidopterous larvæ, is particularly interesting to one who has been working on an allied subject. Recent investigations of my own on the fauna of lead-polluted streams in North Cardiganshire, as reported at the Hull meeting of the British Association, point to the presence of dissolved lead salts in these rivers as distinctly inimical to the aquatic population, in particular to the larvæ of certain insect-groups, such as Trichoptera, which are normally non-existent in these streams, though well represented in their neighbours.

The case of fattening of Weardale sheep on lead-polluted pastures may perhaps provide a parallel, while it is quite possible that small doses of lead may have a tonic effect, cases of lead-poisoning proper among farm live-stock in general are common in certain districts (see a paper on "Plumbism in N. Cards" by E. Morgan, *Journal of U.C.W. Agricultural Dept.*, 1915), and usually the poisoning is of the type known as "chronic," the effect being slow and cumulative, as is also established in the case of lead-poisoning as an industrial disease. It would be interesting to know whether Dr. Garrett's experiments have extended over more than one generation of Lepidoptera, and whether the reproductive faculties were in any way affected.

Polar and Non-Polar Valency in Organic Compounds.

THERE is an increasing tendency on the part of organic chemists to apply the Berzelius dualistic theory, in a modified form, to organic compounds. In many theories of valency, individual groups are considered to be more or less electropositive or electronegative, and it is possible to arrange these groups, approximately, in a table of descending electropositive character. A difficulty which arises in examining this conception is to visualise the transference of anything less than one electron between the group and the remainder of the molecule. There appear to be at least two kinds of forces operating between atoms in a molecule, which can

be designated as polar and non-polar. The polar character of the valency in the majority of salts is definite, there is experimental evidence for the transference of electrons in these substances. The non-polar forces are particularly in evidence in the linkings of organic compounds, and it is extremely unlikely that transference takes place to an appreciable extent here. Without entering into a discussion of the nature of the non-polar forces, which may be electromagnetic, there are two explanations which may be given of the undoubted positive and negative relationships of groups in organic compounds. In the first place, there may be a partial transference of an electron between the group and the residue of the molecule, or alternately there may be a varying concentration of polar molecules in the typically non-polar substance.

I venture to put forward a plea for the consideration of this second possibility. An equilibrium may be imagined to exist between the polar and non-polar substances which will be affected by the temperature, solvent in which it is dissolved, etc. Thus, in an organic substance AX the equation,

$$\overset{-}{A}\overset{+}{X} \rightleftharpoons AX \rightleftharpoons \overset{+}{A}\overset{-}{X}$$

may represent this kind of equilibrium, and the more electronegative the group X the more will this reaction proceed to the right. In those substances where the stability of the non-polar arrangement is very great, the occurrence of both forms, $\overset{-}{A}\overset{+}{X}$ and $\overset{+}{A}\overset{-}{X}$, will be possible, and in the presence of a suitable solvent these may give rise to the respective ions. This view is in agreement with the occurrence of a group in some compounds with an electropositive, and in others with an electronegative tendency. The ease of replacement of the group X by another group will be determined by the concentrations of the polar body, the polar state being the active form of the substance. These concentrations may be so small as to escape the ordinary methods of measurement, and yet be sufficiently great to explain the velocity of the chemical action.

The X-ray Structure of Potassium Cyanide.

WRITING in a contemporary (J.A.C.S., Feb. 1922), Richard M. Bozorth gives details of X-ray investigations into the crystalline structure of KCN, and corroborates the view expressed in a letter to this journal (NATURE, Aug. 11, 1921, vol. 107, p. 715) that the underlying structure is the face-centred cube. He gives 6.55 Å as the length of its edge, which agrees very well with the 6.54 Å furnished by my measurements. He goes further in that he assigns definite positions to the carbon and nitrogen atoms and questions the opinion, expressed by Langmuir, that these constituent atoms of the CN radicle have a common outer electron shell.

Bozorth's conclusions are, to a certain extent, based on the assumption that the relative intensities of the spectra would fall off in a normal manner if the structure were quite like that of NaCl, that is, if the carbon and nitrogen atoms formed a single cluster of electrons which occupied the same position in the KCN structure as the chlorine atom does in NaCl. He publishes no numbers representing the observed intensities, but gives 100 : 10 : 3 as the relative values of the [100], [200], and [300] reflections that would be required to satisfy the requirements of his particular structure. My own measurements gave 16-17 as the relative value to be assigned to the [200] reflection, and the corresponding figure for NaCl is 20. Now the fact that KCN has a lower fusing-point than NaCl suggests that even at ordinary temperatures the heat vibrations are of unusual amplitude, and this in itself affords a ready explanation of the fact that the intensities of the spectra die away more rapidly than is normally the case. The probable electron distribution in a composite CN radicle is another important factor which would cause the normal sequence to fall off rapidly.

Bozorth gives 1·15 Å as the distance between the centres of the carbon and nitrogen atoms, and 3·0 Å as the distance between either of these and the potassium atom. He treats the carbon and nitrogen atoms as though they were of the same size, but he does not state whether or not the inter-nuclear distance is to be taken also as the effective diameter. In one case his figures would give 4·85 Å as the diameter of the potassium atom compared with 4·15 Å, which represents, probably to within 0·03 Å, its value in the other ionised salts in which it occurs (W. L. Bragg, *Phil. Mag.*, Aug. 1920). If, on the other hand, 4·15 Å be accepted as its diameter in KCN—and measurements on NaCN justify this procedure—then Bozorth's figures would give 1·85 Å as the effective diameters of both carbon and nitrogen; W. L. Bragg's values are 1·54 Å and 1·30 Å respectively.

Fortunately, there is outside evidence which bears directly on this question. From viscosity measurements A. O. Rankine has found (Proc. Roy. Soc., July 1921) that the C_2N_2 molecule behaves in collision like two overlapping hard spheres, each having the size of a bromine atom. The diameter of the bromine atom is 2·38 Å, and that of a Langmuir CN radicle, as provided by X-ray measurements, is 2·39 Å.

Sex Change in Mollusca.

WITH reference to Dr. R. Sparck's statement (NATURE, October 7, p. 480) that the male stage in the oyster is due to the coldness of the temperature, it should be pointed out that in various hermaphrodite mollusca, such as Helix and Arion, the reason for the passage of the indifferent epithelial cell, either to oogonium or spermatogonium, is at present unknown. Older authors considered that those cells near yolk, or near a superior nutrimental radius became eggs, and that those less exposed to steady streams of nourishment became spermatocytes.

More recent work has shown that the matter is very deep-seated, and such a conclusion as the above cannot be taken as representing the real state of affairs. I have found that oocytes appear in regions of the ovotestis which are scantily provided with yolk, and that sperm cells appear in regions rich in nutriment.

Whether temperature has anything to do with this has not yet been ascertained, but experiments are now in progress, which should settle the question.

In the case of Saccocirrus it has been shown that spermatocytes caught up and enclosed in yolk cells have their metabolism so altered that they assume the appearance of oocytes, together with nucleolar extrusions characteristic of the typical oocyte.

But in Helix two epithelial cells side by side often metamorphose, one into an oogonium, another into a spermatogonium, and one seems obliged to believe that factors other than temperature or abundance of nutriment are concerned. J. BRONTË GATENBY.

The Galactic System.[1]

By Dr. HARLOW SHAPLEY.

I.

THROUGHOUT the known sidereal universe there is, among material bodies, an obvious associative tendency, which we see well illustrated in meteor showers, in satellite and planetary systems, in binary stars, and in larger stellar groups such as the Pleiades. These various products of gravitational ordering are clearly but parts of still greater systems, and one of the most fascinating of astronomical studies is to attempt to seek out the structure of an all-inclusive sidereal organisation.

It is proposed in this communication to discuss the structure and extent of the sidereal system as indicated by recent studies of stellar clusters and variable stars. My own observational investigations of these objects, and the deductions based upon them, have been mainly published in Contributions and Communications of the Mount Wilson Observatory [1] from 1914 to 1918. The present discussion is made in the light of criticisms and numerous tests to which the conclusions have been subjected during the past four or five years.

It appears that we have three principal types of celestial objects to consider—the diffuse nebulæ, the stars, and the nebulæ of the spiral family. The first two are generally thought to be related as parent and offspring. The stars, having formed, as we think, out of nebulous pre-stellar states, are, apparently, largely organised into groups, a common, possibly prevailing form being the globular cluster. It is from combinations of these clusters that I believe our galactic system has developed.[2] From the work on clusters there can be little doubt of the enormous mass and dimensions of the galactic system as compared with clusters and nebulæ. Its flat form and heterogeneity, its content of numerous fragmentary systems (open clusters, wide binaries, spectrally-similar groups) of apparently different ages and separate origins, and its control over the motions of the clusters and near-by spirals, have led me for some years to advocate the hypothesis that the Galaxy is a growing composite of disintegrating minor systems. The Galaxy appears to include all the common sidereal types, with the probable exception of most nebulæ of the spiral family. But the latter are apparently not stellar in composition, nor galactic in size. I think present evidence favours but does not establish the hypothesis that typical spiral nebulæ represent a sidereal evolution not directly connected with that of stars.

The foregoing paragraph may serve as a brief outline. Some of the details may now be considered, but, before proceeding with the discussion, I should like to point out that the proposed interpretations involve the following somewhat fundamental assumptions, if we choose to call them assumptions: (1) that gravitation directs the organisation and motions of celestial bodies; (2) that the physical laws we know are equally valid in all parts of the space with which we are familiar; (3) that the Russell-Eddington theory of stellar evolution is correct in its general features.

Certainly these three are not serious restrictions. On the first I need make no comment here. The second is the basis of our belief in the general uniformity of conditions throughout the stellar system. It insists that our stellar neighbourhood is not operated by local laws. It is a highly reasonable but necessary assumption before we can safely compare the luminosities and other properties of stars near the sun with those of stars in distant parts of the galactic system. The third assumption, the Russell-Eddington theory, is not necessary for my conclusions concerning the dimensions of the galactic system, but is essential in putting together the general scheme, and also in tying to interpret some anomalies of the spiral nebulæ. We might call the evolutionary scheme the Lane-Lockyer-Ritter-Sampson-Emden-Schwarzschild-Hertzsprung-Russell-Eddington-Jeans-Eggert theory, but Russell and Eddington have been the most important contributors to the theory in its present form.

CONCERNING STAR CLUSTERS.

Clusters of stars can be placed in two fairly distinct categories, the globular cluster, of which nearly ninety are now known, and the open or loose cluster, of which there are several hundred.

Most globular clusters (but not quite all) appear to be remarkably alike in general structure. Compared with naked-eye objects they are extremely remote, hence their stars, though apparently very faint, are actually of high intrinsic luminosity. Few stars in globular clusters are brighter than the eleventh apparent magnitude. Each globular cluster contains some tens of thousands of these intrinsically bright stars, and possibly a far greater number of dwarfs, which at present are beyond the reach of our telescopes. Of high importance is the fact that the cluster stars appear to be remarkably similar to the stars in the solar neighbourhood in spectral type, colour, variability, and other properties, notwithstanding the much higher stellar density near the centres of globular clusters.

Open clusters are of great variety. They range in brightness from naked-eye systems, such as the Hyades, to small, dim groupings that may be nothing more than chance aggregations of faint Milky Way stars. Open clusters vary also in richness, in apparent and real dimensions, in stellar content. One property they have in common—they are all near the plane of the Milky Way. The distance of the average open cluster is smaller than that of globular clusters, but the determination of distances for the former is generally subject to much uncertainty. This fact is due to variety of form and content, and to the absence from open clusters of peculiar types of highly luminous stars, which for globular clusters serve to determine positions in space.

The estimation of the distances of globular clusters, which has been the most important part of the work on the scale of the sidereal universe, must be based on the newer methods of measuring space. The various trigonometrical methods, when applied to globular clusters, so far give negative results, indicating only that the distances are very great. The various photo-

[1] Adapted from an Address given before the British Astronomical Association on May 31.

metric methods that had to be developed for this problem involve a considerable amount of photometric, spectroscopic, and statistical detail when put on a quantitative basis, and cannot be fully described in this article.

The qualitative application of the photometric methods, however, is simple. For example, we need only assume that the brightest stars in a globular cluster have the same actual luminosity as the brightest stars in the solar neighbourhood, and we can readily compute the distance necessary to give them the apparent brightness that is measured.

If we admit the similarity of globular clusters, it is obvious that either the apparent magnitude or the apparent diameter can give us the distances of them all when once we have determined the distances of those nearer the earth. In practice the distances of the nearest clusters have been determined from studies of their variable stars, of their blue stars (spectral type B), and of their red giant stars; and checked by spectroscopically-determined absolute magnitudes and by means of the relative diameters. All the methods agree in giving distances of the same order of magnitude. We thus find that the globular clusters range in distance from seven thousand parsecs to values nearly ten times as great. Their diameters are of the order of a hundred parsecs. Their brightest stars are a thousand times as bright as the sun.

The Structure of the Galaxy.

The result of most interest that comes out of this photometric investigation is the enormous dimensions of the super-system of globular clusters and of the Galaxy. Once the positions in space are determined, it becomes clear, as had already been suspected from an inspection of the apparent distribution of clusters in the sky, that globular clusters are a part of the Milky Way system. They are associated physically with the system of stars, nebulæ, and open clusters which is more or less symmetrically arranged with respect to the equatorial plane of the Galaxy. In measuring the distances of the remotest globular clusters, therefore, we are but measuring the depth of our own galactic system. That the Milky Way itself extends to distances as great as those indicated by the clusters is shown by the presence within it of highly luminous types of stars with apparent magnitude 15 and fainter.

It has been known for many years that globular clusters are not uniformly distributed in galactic longitude. They are most numerous along the edges of the southern Milky Way. That one-sided distribution is now recognised as an indication of the sun's very eccentric position in the galactic system. In this same southern part of the sky we find the densest galactic star-clouds and the greatest frequency of faint novæ and of other types of distant objects, which is but further evidence of the greater depth of the galactic system in the direction of Sagittarius. Also in that general direction are some obstructing dark nebulæ, which may be wholly responsible for a peculiar phenomenon in the distribution of distant globular clusters, that is, in their seeming absence from regions very close to the galactic plane. If the obstructing material were removed, we might see, near the galactic plane, clouds of faint Milky Way stars still more dazzling than those observed, and globular clusters still more distant than those now known, and hence find that the greatest diameter of the galactic system is even larger than the value now assigned—approximately 100,000 parsecs.

The observable dynamical relations within and without the Milky Way are suggestive of its origin. No open clusters have yet been found outside the Milky Way region, but hundreds are known within. North and south of the galactic plane the globular clusters are equal in number, and their distances from the plane are much smaller than the greatest diameter of the system. Their velocities, so far as now known, are high. Many are approaching the galactic plane with speeds that soon must bring them to it. Their present positions and motions make orbital motion around the Milky Way improbable. From the present evidence as to mass, velocity, and distribution, there can be little doubt but that the known globular clusters pass to and fro through the star fields of the galactic system, notwithstanding their observed avoidance, apparent or temporary, at the present time. Every passage must reduce the velocity and alter the form. The hypothesis that these globular clusters are being diverted by degrees into galactic regions, and gradually robbed of their stars, is upheld by observation and is not opposed by present dynamical theory. Although we see few intermediates between the globular and the more typical open clusters, many of the characteristics of the open groups strongly support the suggestion that they are the remnants of globular clusters or of other systems that have been assimilated by the incomparably more massive galactic assemblage. Nearly a dozen "moving" clusters, comprising thousands of members, are recognised among the stars within seven hundred light-years of the sun.

Two important theoretical researches by Jeans are of much significance in this view of galactic structure: (i.) the form resulting from the interpenetration of two clusters,[3] and (ii.) the necessity, in accounting for the present orbits of long-period binaries, of assuming their former existence in a much more compact stellar field than now exists in the solar neighbourhood.[4] The high stellar frequency near the centre of a globular cluster would certainly supply conditions favourable for modifying orbits, and it also might aid in explaining the origin of long-period binaries which is not otherwise accounted for satisfactorily.

The determination, with the aid of clusters, of dimensions for the galactic system much larger than had been clearly indicated by studies of the nearer galactic stars, led to a further examination of the stellar distribution in the solar neighbourhood. The hypothesis that the galactic system, as we now know it, has developed from the combination of minor groups, suggests that the brighter stars near the sun may to a large extent be members of a local system that is imbedded in and moving through the general star fields of the Milky Way. This condition actually appears to be the case, and hence the results on galactic dimensions, from clusters and from the nearer stars, do not contradict. Stars of spectral type B down to the sixth apparent magnitude seem to be almost exclusively members of a local cluster or cloud. Brighter stars of Class A are also affiliated with the same system.[5] Probably all

the other types are to some extent involved,[6] but for them the disentanglement of local system and galactic field is more difficult.

Quite analogous to the phenomenon of the Milky Way, the projection on the sky of the faint stars along the central plane of this local cloud gives rise to a sort of secondary Galaxy,[7] the brighter stars of which coincide roughly with the Herschel-Gould belt. The distribution of the B stars indicates that the dimensions of the local system are large compared with those of a globular cluster; the local system is also more oblate. I believe it can be better compared in dimensions, and possibly in form, with the Magellanic Clouds or with the distinctly delimited small star clouds of the Milky Way. The various phenomena of star streaming are undoubtedly connected with the motions of and within the local system. Probably a number of our brighter "moving" clusters should be considered sub-systems in the local cloud, rather than independent systems which for the time being are near at hand.

(To be continued.)

Transport of Organic Substances in Plants.[1]

By Prof. H. H. DIXON, Sc.D., F.R.S.

AMONG physiologists the usually accepted view is that organic substances are distributed throughout the plant by means of the bast. The wood also acts as a channel of distribution for these substances to opening buds and developing leaves, especially in spring when root-pressure is active. The sap of bleeding contains appreciable quantities of these substances, and their distribution to the developing buds in spring by means of the wood was recognised by Hartig and Sachs.

This upward transport of carbohydrates in the tracheæ seems to be accompanied with smaller amounts of proteins. Thus Schroeder showed that the quantity of proteins in the bleeding sap rises and falls with the quantity of sugar.

This view that the rising current in the tracheæ carries organic substances in it and distributes them to the growing regions has lately been impugned. It was pointed out that in many cases, ringing close below the terminal bud prevents the development of that bud because the wood is unable to transmit sufficient supplies of organic substance. As Strasburger has already shown, this interpretation rests upon the fallacy of supposing that the removal of the bark as far as the cambium leaves the wood uninjured As a matter of fact, microscopic examination of the wood, from which the outer tissues have been stripped, shows that its tracheæ soon become blocked with air-bubbles and with substances probably exuded into them and their walls during morbid changes in the cells of the cambium, in the cells of the medullary rays, and in those of the wood-parenchyma The blocking is accompanied with discoloration, and is most apparent in the outer layers of the wood. It is only reasonable to suppose that the efficiency of the tracheæ as channels of transmission is seriously impaired even before there is visible evidence of plugging.

It is evident that this clogging may act differentially on the water and the substances carried in it. In the first place, the whole cross-section of the wood is available for the transport of water, while probably the outer layers are mainly utilised by the organic substances Further, colloidal deposits in the walls, and especially in the pit-membranes, would obstruct the passage of organic substances much more than they would the water which carries them These considerations readily explain how it is that, while the water-supply to the buds of ringed branches is adequate, the supply of organic substance may be deficient.

Apart, then, from the very slow movement of organic substances from cell to cell, there is very cogent evidence that their upward motion is effected in the tracheæ of the wood. There is no reason to believe that during this transport the walls or pit-membranes of these tracheæ oppose the passage of the dissolved carbohydrates or of the simpler proteins any more than the water which conveys them. Hence the velocity of transport of these organic substances is that of the transpiration current, and the amount conveyed in a given time depends on the velocity and concentration of the stream.

The transport of organic substances in an upward direction in plants is secondary, for, as is well known, carbohydrates certainly, and proteins most probably, are manufactured only in the upper green parts of plants—principally in the leaves, and must be transported in the first instance back from these to the stems to be distributed to the growing regions and to the storage organs

This view that the channel for the backward and downward movement of organic substances is afforded by the bast received great support from Czapek's work published in 1897 By section of the conducting tracts in one half of the petiole he showed that depletion of the corresponding half of the blade was delayed. He also showed that only where vertical bridges connected the upper and lower portions of bark in ringed stems were the effects of ringing nullified Oblique and zigzag bridges are ineffective. Thus transverse conveyance in the stem is negligible. The parallel and longitudinal arrangement of the elongated elements in the bast seemed to him to provide adequately for the observed longitudinal passage Then narrowness and large colloid content did not present themselves as difficulties. Czapek also recorded the observation that the blades of leaves, the petioles of which had been killed by jacketing them with steam, did not become emptied of starch. Similarly, when the petioles were killed with chloroform-vapour, depletion was arrested. Again, anæsthetisation of the petiole, by surrounding

[1] From the presidential address delivered to Section K (Botany) of the British Association at Hull on Sept. 7.

it with a watery solution of chloroform, greatly delayed the disappearance of starch

Czapek formed no definite theory as to how organic substances were moved in the bast. He was sure that the transport depends on living protoplasm He did not consider that the streaming of protoplasm contributed materially to the motion, seeing that streaming does not occur in mature sieve-tubes He regarded the sieve-tubes as the most important elements in the transmission of these substances, because the deposition of callus in the sieve-plates synchronises with the stoppage of transport The transport, according to him, is not simply due to diffusion He supposed the protoplasm to take up the organic substances and pass them on If diffusion does not account for the passage from one particle of protoplasm to the next, it would seem that we must suppose the organic substance to be projected from one to the other.

These observations and their interpretation by Czapek have strengthened the opinion that the bast is the channel for the downward transport of organic substances It is remarkable how little weight has been attached to the damaging criticism of Czapek's views by Deleano, especially as those views are so unsatisfactory from a physical point of view.

The latter author showed that it is inadmissible to compare externally similar leaves, which often behave, so far as depletion is concerned very dissimilarly He also pointed out that without any export a leaf may be depleted of all its starch within thirty-five hours, and partially anticipated an extremely interesting recent observation of Molisch—namely, that transpiring leaves lose their carbohydrates much more rapidly than those the transpiration from which is checked by being surrounded with a saturated atmosphere Neglect of these facts led Czapek into error Deleano also showed that organic substances continue to leave the blades even after the petioles have been killed by heat or by chloroform-vapour The rate of depletion is reduced by the former agent to about one-third, and by the latter to one-half If this observation is substantiated it would show that the intervention of living elements is not essential for the transport He further found that the blades attached to petioles which were surrounded by chloroform-water lost their starch more quickly than those immersed in water

The contradictory conclusions of Czapek and Deleano urgently call for a reinvestigation of the points at issue. If Czapek's work holds good, we shall have to regard the bast, and especially the sieve-tubes, as the channels for the transport of organic substances back from the leaf-blades where they are manufactured, and we must look for some hitherto undreamed-of method of transmission through these most unlikely-looking conduits On the other hand, if Deleano's conclusions are borne out, we should admit that protoplasm is not necessary for the transport, and we would turn to a dead tissue as furnishing this channel

So far as I am aware none of the earlier investigators made any estimate either of the actual quantities of organic material which are transported or of the velocities of flow in the channels which are necessary to effect this transport

We may approach this problem from two opposite directions—(1) by dealing with the amount of organic substance accumulated in a given time in a storage organ, or (2) by using the amount exported from an assimilating organ. The cross-section of the supposed channels of transport and the volume of the solution containing the substances in each case will give us the other necessary data.

For the first method a potato-tuber will furnish an example. One weighing 210 g was found attached to the base of a plant by a slender branch about 0·16 cm. in diameter. In this branch the bast had a total cross-section of 0·0042 $cm.^2$ This figure is a maximum, no allowance was made for the cross-section of the cell-walls, or for any non-functional elements in the bast The cell-walls would occupy probably one-fifth of the cross-section of the bast Now if the bast exclusively furnished the channel of downward transport, all the organic substance in the potato must have passed this cross section during the time occupied in the growth of the potato One hundred days would be a liberal allowance. According to analyses more than 24 per cent. by weight of the potato is combustible. Therefore we must assume that during this time more than 50 g. of carbohydrate has passed down a conduit having a cross-section of no more than 0·0042 $cm.^2$. The average concentration of the solution carrying this substance could scarcely have been as much as 10 per cent (2·5-5 per cent would be more probable; the concentration of sugar in bleeding sap is much below this figure, and seems never to reach 4 per cent) Assuming, however, this concentration, the volume of liquid conveying 50 g must have been 500 cm^3 and this quantity must have passed in 100 days Therefore the average velocity of flow through this conduit, having a cross-section of 0·0042 cm^2, must have been

$$\frac{500}{0{\cdot}0042 \times 100 \times 24}, \text{ i.e. nearly 50 cm. per hour}$$

By the second method we arrive at a different figure. Various investigators, from Sachs onwards, have measured the rate of photo-synthesis per square metre of leaf per hour. Under the most favourable conditions the amount may approach 2 g., and it has been estimated as low as 0·5 g. Taking Brown and Morris's determination for *Tropaeolum majus*, namely, 1 g per square metre per hour, and assuming one third of the carbohydrate formed is used in respiration in the leaf, we find that a leaf of 46 cm^2 may form during ten hours' sunshine 0·46 g, during the twenty-four hours one-third of this will be respired, leaving 0·31 g to be transported from the leaf The volume of the solution (again assuming a concentration of 10 per cent) will be 3·10 cm^3 The cross-section of the bast of the bundles in the petiole was 0·0009 cm^2, therefore the velocity of flow, if the bast was used as the channel of transport, must have been $\frac{3{\cdot}10}{0{\cdot}0009 \times 24}$ or 140 cm. per hour

Similar figures to these were derived using measurements obtained from a number of potato-tubers and from various leaves. The velocities indicated, even assuming a concentration of 10 per cent., lay in all cases between 20 cm. and 140 cm. per hour. These figures are in agreement with those arrived at by Luise Birch-Hirschfeld, as to the weight of organic material transported from leaves.

A flow of this rate through the bast seems quite

impossible. The narrow transverse section of its elements, the frequent occurrence of transverse walls, and the lining of protoplasm and large protein contents practically preclude the mass movement of liquid through this tissue. If we imagine the flow restricted to the sieve-tubes the velocity must be correspondingly increased, and the excessively fine sieve-pores, more or less completely occupied by colloidal proteins, must be reckoned with. Simple diffusion, as Czapek recognised, cannot account for the transport, and there is no reason to suppose that adsorption on the surfaces of the colloid contents of the sieve-tubes can increase the velocity of diffusion, as Mangham suggests.

As soon as one realises the volume of the solution which has to be transported, and the velocity of the flow that this necessitates, one naturally turns to consider if the open capillary tubes of the wood may not be utilised as channels of transport. Deleano's results, indicating that the depletion of leaves continues even after the living elements of their petioles have been killed, support this conjecture.

The emphasis which has been laid on the function of the wood as providing a channel for the upward movement of water usually obscures its function as a downward and backward channel also. Early experimenters, however, fully recognised that, under certain conditions, the current in the wood may be reversed. There is, of course, recent work also showing this reversed current.

By means of an eosin solution this reversal of the transpiration current may be very easily demonstrated. If the tip of a leaf of a growing potato-plant is cut under eosin solution, the coloured solution is very quickly drawn back into the tracheæ of the conducting tracts of the leaf; from there it passes into those of the petiole, and makes its way not only into the upper branches and leaves, but also passing down the supporting stem may completely inject the tracheæ of the tuber, and from thence pass up into the wood of the remaining haulms of the plant. Its passage is entirely in the tracheæ of the wood of the conducting tracts.

Another very striking experiment may be carried out with the imparipinnate leaf of *Sambucus nigra*. Its petiole is split longitudinally for a few centimetres and half removed. The remaining half is set in a solution of eosin. The solution is rapidly drawn up the wood-capillaries of the intact half-petiole and soon appears in the veins of the pinnæ on the same side of the leaf, beginning with the lowest, and gradually working up into the upper ones. Finally it appears in the terminal pinna. All this while the veins of the pinnæ on the other side remain uncoloured. Now, however, the eosin begins to debouch into the base of the uppermost of these pinnæ and spreads through its veins; finally it makes its way down the offside of the rachis to the bases of the lower pinnæ, and from thence spreads into their veins. In this case we see very clearly how transpiration actuates an upward current on one side and a downward current on the other. It is interesting to note that if the terminal pinna and its stalk is removed the eosin does not appear in the pinnæ of the second side, or only after a considerable time, when the small anastomosing conducting tracts are utilised.

Luise Birch-Hirschfeld also described recently many experiments with herbaceous and woody plants, tracing the path of the reversed current by means of lithium nitrate and eosin.

In all these cases the tension of the sap determines the flow from a source wherever situated, and transpiration from the leaves, or parts of leaves, which are not supplied with liquid water from without, draws the water through the plant along the channels of least resistance. Hence it is that if the cut vein of a lateral pinna provides the point of entry, the solution may pass backwards in some of the conducting tracheæ, leaving others quite uncoloured, so that some of the veins only of the pinna are injected. The injected tracts bring the solution down the rachis and petiole into the stem, while a few or many, as the case may be, remain filled with colourless liquid, presumably the sap drawn upward to supply the transpiring surfaces of the leaf. Generally the coloured liquid descends an appreciable distance in the tracheæ of the stem before it begins to rise in the ascending current, mounting to other transpiring leaves. As a rule after some time (depending on the rate of transpiration and the amount of water supplied by the roots) the presence of the coloured liquid may be demonstrated in certain continuous series, or filaments of tracheæ, in several bundles of the lower parts of the stems. Similarly, if tubers or rhizomes are present, examination of these parts, after a suitable interval, will show that many of their filaments of tracheæ are injected. Meanwhile the parts above the supplying leaf become coloured, and it will be seen that the distribution of coloured tracheæ is decided by the anatomical connexions of those filaments of tracheæ which convey the coloured liquid directly from the point of supply through the petiole to the stem. In tracing the path of the solution one is impressed with the fact that the path of least resistance is by no means always the shortest path in the wood. Transverse motion across several tracheæ seldom occurs, and the separate linear series of conducting tracheæ are practically isolated from each other laterally. Here we may recall Strasburger's experiments showing the very great resistance offered to the flow of water in a transverse direction in the wood of trees. This isolation of the separate filaments of tracheæ in the leaf and in the stem enables the tension developed by the transpiring cells of the leaves, while it raises a column of water in one series of tracheæ, to draw down a solution in a neighbouring filament of tracheæ terminating above in some local supply. If the anatomical connexion of the two series is located in a subterranean organ the tracheæ of the subterranean organ may become filled from that supply.

So far the evidence of reversed flow in the water-conducting tracts which we have been considering has been derived from plants under artificial conditions—plants the conducting tracts of which have been cut into and otherwise interfered with. Is there any evidence that reversal of the transpiration current normally occurs in uninjured plants?

Some recent work on the transmission of stimuli seems to me to indicate that these reversals are continually occurring in normally growing plants.

The first piece of work to which I would direct attention is that of Ricca on Mimosa. It has long been known that the stimulus which causes the folding of the

pinnules and the bending of the petioles of Mimosa could traverse portions of the petioles or stems which had been raised to such a temperature as would kill the living elements in these organs. Notwithstanding that observation, Haberlandt's view, that the stimulus is transmitted as a wave of pressure through certain tubular elements of the bast, was generally accepted as the least objectionable of any of the theories which had been put forward to explain this transmission. Ricca saw that, among other difficulties, the slowness of transmission—never more than 15 mm. per second—was a grave objection to this view. Accordingly, working with a woody species of Mimosa—*Mimosa Spegazzinii*—he removed the whole bast and outer tissues of the stem for as many as twenty-three centimetres and was able to show that the stimulus was still transmitted. Similarly he found that the stimulus was transmitted through narrow strips of the wood from which even the pith had been removed. These experiments and others in which the transmitting organ had been killed for a considerable length caused Ricca to recognise that the stimulus is transmitted in the wood and not in the bast, as had been previously held. Thus he was led to assign the transmission to the transpiration-current. He was able to confirm this conjecture by showing that the transmission to the various leaves of a plant is largely controlled by the rate of the transpiration from the individual leaves. Thus, other things being equal, a rapidly transpiring leaf receives the stimulus sooner than a sluggishly transpiring one equidistant from the point of stimulation. He was able to show further that the stimulus may be transmitted through a glass tube filled with water, just as it is transmitted through a dead portion of the stem. Evidently a hormone set free into the transpiration-stream is the long-sought-for mechanism by which the stimulus is transmitted throughout Mimosa.

As the stimulus travels both in a basipetal and acropetal direction we may assume that movement of the transpiration-stream in a downward direction is of normal occurrence in plants.

Contemporaneous with, and subsequent to, Ricca's important work on Mimosa, experimental evidence has been accumulating to indicate that the transmission of other stimuli—phototropic, traumatotropic, thigmotropic, and geotropic—is effected by means of the passage of a dissolved substance. Boysen-Jensen appears to have been the first to announce that phototropic and geotropic stimuli may be transmitted across protoplasmic discontinuities. Paál emphasised this by showing that these stimuli are able to pass a disc of the tissue of *Arundo donax* impregnated with gelatine, which is interposed between the receptive and responding regions. These observations rendered the view that the stimulus is transmitted in the form of a hormone extremely probable; and later Stark showed that this hormone is thermostable, just as Ricca had done in the case of the hormone of Mimosa. Another very interesting point discovered by Stark—working with traumatic stimuli—is that the hormones are to a certain extent specific. Thus if the perceptive tip of a seedling is removed from one plant and affixed in position on another, the certainty of the response depends on the genetic affinity of the two plants.

In all these cases it seems certain that the perceptive tissues are the point of origin, when stimulated, of a dissolved substance, the hormone, which makes its way to the motile tissues and releases the response.

In the case of Mimosa just alluded to, and of the labellum of Masdevallia examined by Oliver, there is direct evidence that the transmission of the hormone is effected by the vascular bundles. In Mimosa the channels are more precisely localised as being the tracheæ of the wood. Furthermore, the rapidity of transmission renders it certain that simple diffusion through the tissues of the plant will not account for the process. Some recorded velocities of transmission are here enumerated for the sake of comparison:

Plant.	Nature of Stimulus	Transmission Time in secs. per mm.
Mimosa	Heat	0·07
Drosera	Chemical	6·00
Seedling	Light	180-300
"	Gravity	300
Tendril	Contact	17
Diffusion in tissue		2230-3600

There is thus every reason to believe that the transmission of stimuli generally through the tissues of the higher plants is effected by the conveyance of a hormone in the wood of the vascular bundles from the receptive to the motile regions, and whenever this transmission is in a downward direction evidence is afforded of the downward movement of water in the tracheæ. It is reasonable to suppose that this downward current is able to carry organic foodstuffs as well as hormones.

Thus the evidence for the existence of a backward flow of water in the tracheæ of wood, in addition to the more obvious upward stream, is convincing. With regard, however, to the mechanism by which the backward stream is supplied we have but scant information.

The volume-changes of leaves which Thoday has recorded are suggestive in this connexion. These changes he found of various magnitudes, occurring simultaneously in different or in the same leaves. They may cause a linear contraction amounting to 2·5 per cent. in ten minutes, and may produce a volume contraction of 7 per cent. in the same time. The water corresponding to this volume-change in the cells of the leaf if transmitted into the tracheæ would produce a considerable downward displacement, as may be seen from the following figures:

Name of Plant.	Volume of 1 per cent. Contraction in mm^3	Cross-section of Tracheæ in Petiole in mm^2	Downward Movement in cm.
Aucuba japonica .	22·8	0·05	45·6
Solanum tuberosum	28·0	0·07	40·0
Syringa vulgaris .	42·15	0·013	16·5
Acer macrophyllum	12·2	0·22	19·2

If these changes in volume are caused by, or accompanied with, a development of permeability of the contracting cells, evidently a backward movement of organic substance having a velocity of about 120 cm. and more per hour would be produced.

It is possible that the tension which causes these contractions of the leaf-cells at the same time acts as a stimulus to increase the permeability of the plasmatic membranes of the cells; and so one might imagine that the development of a certain tension would automatically release organic substances from the cells and draw them through the tracheæ downwards. Direct experiment on this point presents difficulties, but it may be worth recording that when the internal osmotic pressure of the leaf-cells was overbalanced by an external gas-pressure, the water pressed from the cells and forced out of the tracheæ of the supporting stem was found to be practically pure, and if it contained carbohydrates they were in such small quantities that no reduction could be detected with Benedict's solution either before or after inversion. This experiment was repeated several times with branches of *Sambucus nigra* and *Tilia americana*. The cut branch, well supplied with water, was first exposed for several hours to conditions favourable to photosynthesis, and then either immediately or after a sojourn in darkness subjected to the gas-pressure. A pressure of thirteen atmospheres was found sufficient to drive water back from the leaves out of the stem.

Of course the conditions of this experiment are not those obtaining in the normal plant, where during transpiration the volume of a leaf, or part of a leaf, changes. In the transpiring plant we can also imagine the accumulation of a substance or an ion which would give rise to an alteration of the permeability of the plasmatic membranes of the leaves.

When, in order to imitate these conditions, the cells of the leaves in the foregoing experiment are rendered permeable by the introduction of a little toluene into the pressure-chamber, the application of a smaller pressure is sufficient to press the cell-contents into the water-channels and liquid emerges from the base of the stem which readily reduces Benedict's solution.

In the same way, if a pinna of *Sambucus nigra* is surrounded with toluene vapour, transpiration from the adjacent pinnæ draws back the cell-contents of the toluened pinna, and afterwards their track in the wood of the vascular bundles of the rachis may be traced by the browning of this tissue.

Another possibility presented itself, namely, that the direction of the current might act as a stimulus regulating the permeability of the cells in contact with the tracheæ. To test this, short lengths of stem set in their normal position were supplied, first through their lower and afterwards through their upper end, with distilled water. In neither case could carbohydrates be detected in the issuing stream.

The foregoing short consideration of some recent physiological work leads us, then, to the following conclusions:

The transport of the organic substances needed in the distal growing regions is effected through the tracheæ of the wood. The substances travel dissolved in the water filling these channels, which is moved by transpiration, expansion of the growing cells, or root pressure.

Physical considerations forbid us admitting that sufficiently rapid transport can be afforded by the bast either for the observed upward or downward distribution of organic substance.

The existence of downward as well as upward movement of water in the tracheæ of the wood may be demonstrated by suitable experimental means, and may be inferred by the transport of hormones in the wood.

The occurrence of local contractions in leaves suggests that local increases of permeability supply dissolved organic substances to the distal ends of certain of the filaments of tracheæ. The tension developed by the transpiration of other regions draws these along downward as well as upward channels in the wood.

In thus ruling out the participation of the bast in the longitudinal transport of organic substances in plants one naturally is forced to speculate on its probable function. Its distribution and conformation are such that, while it possesses a very small cross-section, it appears with the other living elements of the vascular bundles, medullary rays, wood-parenchyma, etc., to present a maximum surface to the tracheæ.

This large surface may find explanation in the necessity of interchange between the living cells and dead conduits. The colloidal contents of the former render this process slow, hence the necessity for the large surface of interchange to enable sufficient quantities of organic substances to be abstracted from and introduced into the tracheæ to meet the needs of the plant.

Before concluding I would like to add that the experimental work carried out on this matter would have been quite impossible for me were it not for the assistance and ingenuity of Mr. N. G. Ball. He also has contributed materially by his criticisms and suggestions.

Obituary.

COLONEL E. H. GROVE-HILLS, C.B.E., C.M.G., F.R.S.

COLONEL EDMOND HERBERT GROVE-HILLS, whose death occurred on October 2 at his residence at Campden Hill, W., was the son of Herbert A. Hills of High Head Castle, Cumberland. Born on August 1, 1864, he was educated at Winchester, whence in 1882 he passed into the Royal Military Academy, Woolwich. There his abilities were recognised as giving promise of a distinguished career, and he passed out as the senior cadet of his term, receiving a commission in the Royal Engineers in 1884.

Scientific subjects specially interested him, and in 1893 he was elected a fellow of the Royal Astronomical Society; in the following year a paper by him on the photographs of the spectrum of the eclipsed sun taken at the solar eclipse of April 1893 was communicated to the Royal Society. The study of solar physics strongly attracted him, and he also took part in the eclipse expeditions of 1896 to Japan, of 1898 to India, and in that of 1914 to Kieff, whence he was recalled on the outbreak of war to military service. In 1898 he took up the appointment of instructor in chemistry and photography at the School of Military

Engineering, but he had only held this for a year when he was transferred to the Topographical Section of the General Staff at the War Office. Here his scientific inclinations found full scope in the organisation of survey work in all parts of the world. During his tenure of the post he raised the standard of this work in a very notable degree, which was recognised by the C.M.G. being conferred on him in 1902. His work here brought him into contact with many problems in geodesy, in which he took a keen and lasting interest. At this time Sir David Gill was actively promoting the geodetic triangulation in South Africa, and to this Grove-Hills gave his whole-hearted support.

In 1905 he completed his period of service as head of the topographical department of the War Office, and then retired from the army. In the following year he contested Portsmouth in the Conservative interest unsuccessfully, and afterwards occupied himself mainly with scientific investigations. At the British Association in 1906 he raised the question whether the triangulation of this country was of the accuracy required by modern geodesy, and a few years later the Ordnance Survey undertook the re-observation of certain triangles in Scotland to determine this point. In the same year he and Sir Joseph Larmor discussed the movement of the pole in an important communication to the Royal Astronomical Society.

Col. Grove-Hills was president of Section E at the British Association meeting in 1908, where he discussed the surveys of the British Empire in an important address. He had before this been invited to report on the Canadian surveys and wrote a valuable and instructive report on them. In 1911 he was elected a Fellow of the Royal Society, and from 1913 to 1915 he was president of the Royal Astronomical Society. He was also latterly Secretary of the Royal Institution. Keenly interested in astronomy, he designed the suspended zenith instrument at Durham Observatory, of which institution he was Honorary Director up to the time of his death. While on his way to Kieff with the eclipse expedition of 1914 he was recalled to take his part in the Great War, and was appointed Assistant Chief Engineer of the Eastern Command, being gazetted Brigadier-General in 1918. His services in this responsible post were recognised by the award of the C.B.E. in 1919.

Endowed with very great natural ability, and a keen interest in all scientific questions, Grove-Hills combined with these great administrative ability and sound common sense. He was always ready to assist by his advice and active co-operation in any well-planned scheme of scientific work, and in his death astronomy and geodesy have suffered a severe loss.

H. G. L.

MAJOR-GENERAL J. WATERHOUSE.

MAJOR-GENERAL JAMES WATERHOUSE, who was eighty years of age, died on September 28. As a youth he joined the Royal Bengal Artillery, and after seven years was made Assistant Surveyor-General in charge of the photography section in the Surveyor-General's Office in Calcutta. He retired in 1897. His official duties necessitated the study of photography and photo-mechanical methods of reproduction, and this he did with a keen eye for any possible improvement, and a skilful hand which enabled him to test the practical value of any new introduction. He made an extended continental tour during his term of office that he might become acquainted with the methods employed in foreign photographic laboratories. A considerable number of improvements were introduced by Waterhouse in photolithography and allied processes, as well as in collotype, sometimes varying methods in use elsewhere to render them suitable for a tropical climate. His knowledge of these methods in all their minutiæ was very extensive, and in 1882–1885 he contributed to the *Photographic News* a series of fifty chapters on photolithography.

In 1873, when Vogel published his discovery that the sensitiveness of plates to green and red could be enhanced from a negligible to a practically useful amount by the use of certain dyes, Waterhouse was one of the very first to confirm the observation and to find other effective dyes. In 1890 he found that by the addition of thiourea to the developer the reversal of the image was so much facilitated that a very little, if any, increase of exposure was necessary. He took part in the observation of the total eclipses of 1871 and 1875, and in the transit of Venus in 1874.

On his retirement, Waterhouse studied the early history of the camera obscura, and of the action of light on silver salts, correcting some false and incomplete ideas that were current. He was president of the Royal Photographic Society from 1905 to 1907, honorary secretary of the Calcutta Zoological Gardens from 1894 to 1897, president of the Asiatic Society of Bengal from 1888 to 1890, and trustee and twice chairman of the Indian Museum at Calcutta. The value of his scientific work in connexion with photography was acknowledged by the award to him of the Progress Medal of the Royal Photographic Society, and the Voigtländer Medal of the Vienna Photographic Society.

WE regret to record the death of Prof. J. K. A. Wertheim Salomonson. He was born in 1864, passed his medical studies at the University of Leyden, and in 1899 became professor in neurology and radiology in the University of Amsterdam. His contributions to these two subjects were of considerable importance, for his range of knowledge of medicine and physics was supplemented by a perfection of skill in instrumental design. He was a frequent visitor to this country and only last year he demonstrated to the Ophthalmological Section of the Royal Society of Medicine a method for the photography of the structure of the eye. He was responsible for improvements in the electro-cardiograph and in many instruments designed for radiological purposes. A man of engaging personality, his loss will be felt over the wide circle which his scientific interests served. He was a Knight of the Order of the Lion of the Netherlands and an honorary member of the Röntgen Society. At the time of his death he held the office of rector magnificus at the University of Amsterdam.

Current Topics and Events.

AN announcement was made in the Press on October 10 by the British Broadcasting Company concerning the conditions which, in order to obtain Post Office approval, must be fulfilled by receiving apparatus intended for use in connexion with the broadcasting services. The conditions have been framed with the view of preventing the use, in such sets, of circuits which may "regenerate" oscillations and thus cause disturbances at receiving stations within their re-radiation range. Experience has indicated the need, in the case of receiving apparatus handled by an unskilful user, for some form of control in the type and design of the apparatus of the nature which is aimed at in the specification in question; the specification accordingly should serve a useful purpose. Exception has been taken in some quarters to the provisions contained in clause 10 of the conditions above referred to, on the ground that these particular conditions conflict with the promise made by the Postmaster-General in the House of Commons on July 27 last, to the effect that the owners of "home-made" receiving apparatus and the existing licencees of imported receiving sets would be allowed to use their apparatus for listening-in to broadcasted news, music, etc. This clause provides, *inter alia*, that "All sets sold under the broadcast licence shall bear the registered trade mark of the broadcasting company and the Post Office registered number." It has consequently been assumed that the issue of licences for receiving broadcasted matter will be confined to those who procure listening sets from the broadcasting company. It appears to have been overlooked, however, that the announcement to which attention is directed above has been issued by the British Broadcasting Company and relates alone to the conditions to be fulfilled by the receiving sets which are to be offered for sale to the public by members of that corporation. No declaration has so far been made by the Post Office which in any way indicates that the Postmaster-General contemplates the adoption of a policy at variance with that which he informed Parliament it was his intention to pursue in this matter; nevertheless, it is distinctly unfortunate that, in all the circumstances of the case, an official statement has not been issued by the Post Office setting out fully and frankly what course it is intended to pursue in relation to the grant of licences generally.

THE assignment to science of the proceeds of the first performance of a great play by a leading dramatist is an act which we record with much satisfaction. The play was the remarkable tragedy "Judith," by M. Henri Bernstein, produced at the Gymnase Théâtre, Paris, on October 12, before a brilliant and distinguished assembly, which comprised ministers of State and the chief social and intellectual leaders of the city. The Paris correspondent of the *Daily Mail* states that the receipts were for the benefit of the French Confederation of Scientific Societies, and the *Times* correspondent announces that more than 1000*l*. was raised by the performance. M. Bernstein gave his royalty as author, and Mme. Simone, who took the title part and obtained the greatest triumph of her career, devoted her fee to the same beneficent purpose. We cannot recall any like association of drama with science in Great Britain, and it is difficult to conceive of the proceeds from a first night being devoted to a scientific institution in this country. If, however, Sir James Barrie, Mr. Bernard Shaw, Mr. Oscar Asche, or any other of our leading dramatists or theatre managers should be inclined to follow the example which Paris has given us, we commend to their attention as eminently worthy of support such confederations as the British Association, British Science Guild, and the Conjoint Board of Scientific Societies.

THE August number of the *Journal of Indian Industries and Labour* contains two articles on State control in the field of industrial enterprise. Mr. C. Y. Chintamani, Minister of Education and Industries in the United Provinces, deals with the subject in an article entitled "The Limits of State Aid to Industry," with special reference to the work of the department of which he is in charge, while Mr. A. Y. G. Campbell contributes the first part of an article on the functions of provincial departments of industries in which the whole question of State assistance is reviewed. Mr. Campbell speaks from experience, as he himself held for some years the post of Director of Industries in Madras. Another feature is an extract from the presidential address delivered to the Mining and Geological Institute of India in January 1922 by Dr. Leigh Fermor, officiating director of the Geological Survey of India, in which is described the practical utility of a State geological department. Dr. Fermor declares that in royalties alone the receipts accruing annually to the Provincial Governments and other owners of mineral rights in India in respect of the eight most important minerals, excluding salt and saltpetre, amount to at least 500,000*l*. The *Journal* also contains the usual summarised accounts of the activities of the Provincial Departments of Industries during the preceding quarter.

THE council of the Institution of Mining and Metallurgy has awarded the Gold Medal of the Institution to Sir Alfred Keogh, "on the occasion of his retirement from the Rectorship of the Imperial College of Science and Technology, in recognition of his great services in the advancement of technological education and as a mark of admiration and respect." The council of the Institution of Mining Engineers has awarded the Medal of the Institution to Sir George Beilby, "in recognition of his valuable contributions to science, with special reference to his researches on fuel." The medals will be presented at the combined dinner of the two institutions to be held at Guildhall, London, on November 16, at which the Prince of Wales and several ministers of State will be present.

DR. M. O. FORSTER was entertained at dinner by a number of his chemical friends on October 6 on the eve of his departure to India to take up the duties of his new appointment as director of the Indian Institute of Science at Bangalore. He left England on October 13 by the P. and O. steamship *Morea*.

IT is stated in the *Chemiker Zeitung* of September 14 that Prof. Wieland has been appointed to the editorial board of *Liebig's Annalen* in place of the late Prof. Wislicenus. The board consists, in addition, of Profs. Wallach, Graebe, Zincke, and Willstätter. In the issue of September 26 it is announced that Dr. Noddack has been appointed director of the Physikalisch-Technische Reichsanstalt.

AT the inaugural meeting of the eighty-first session of the Pharmaceutical Society's School of Pharmacy, Bloomsbury Square, on October 4, the Hanbury medal, awarded every two years for the promotion of research in the chemistry and natural history of drugs, was presented to Prof. Émile Perrot, professor of materia medica in the University of Paris.

THE fifth annual Streatfeild Memorial Lecture will be delivered by Prof. C. H. Desch in the Chemical Lecture Theatre of the Finsbury Technical College, Leonard Street, E.C.2, on Thursday, November 2, at 4 o'clock. The subject will be "The Metallurgical Chemist."

THE forty-fifth anniversary of the Institute of Chemistry will be celebrated by a dinner to be held at the Hotel Victoria, Northumberland Avenue, W.C.2, on Friday, November 17.

ON Tuesday, October 10, members of the Circle of Scientific, Technical, and Trade Journalists accepted the invitation of Holophane Ltd. to visit the new showrooms and laboratories, where an address was delivered by Captain Stroud, and a demonstration of the latest scientific devices for distributing artificial light was arranged. In addition to standard types of reflectors for use in streets, factories, shops, etc., several interesting novelties were shown, including the new unit equipped with Chance's daylight glass to produce "artificial daylight." The appearance of coloured surfaces under this light, as compared with that of ordinary electric lamps, was demonstrated in the laboratory, where apparatus for obtaining polar curves of light distribution was also shown in operation. Mr. Leon Gaster, in returning thanks on behalf of the visitors, remarked that the scientific application of light was a subject of general interest to the technical press. Its importance was illustrated by the appointment, in 1913, of a Home Office Committee on Lighting in Factories and Workshops. It was hoped that in future each scientific advance would be brought to the notice of the technical press, which acted as an educational link between the expert and the general public.

THE seventy-sixth annual meeting of the Birmingham and Edgbaston Debating Society was held on October 4. The visitors included Alderman David Davis (Lord Mayor of Birmingham), Dr. R. Wakefield (Bishop of Birmingham), Dr. McIntyre (Archbishop of Birmingham), Mr. C. Grant Robertson (principal of Birmingham University), Mr. C. A. Vince (president of Birmingham Central Literary Association), and Mr. Arthur Brampton (president of Birmingham Liberal Association). Mr. G. Austin Baker was elected president for the ensuing session. Mr. Harry Jackson, the retiring president, delivered an address on "The Trend of Human Development." He showed that whereas in the past the environment and progress of man was limited to tangible things, to-day it extends more and more to regions outside the immediate perceptions of the senses. The views of Einstein, as contrasted with those of Newton, are a typical example and represent a great and intrinsic mental advance. The individual with the super-sensitive faculty in some particular direction must be given the scope and opportunity for the full expression of his genius. Humanity cannot afford to let clever men wear out their genius in providing themselves with the necessities of life. The most advantageous application of national wealth will be the maintenance of those who are able to work in the higher environment of the intellect.

MR. A. RADCLIFFE BROWN has sent us a long letter complaining of the review of his book—"The Andaman Islanders"—in NATURE of July 22, p. 106. The gist of the reviewer's criticism was that Mr. Brown spoilt a good plan—namely, of stating his own observations and where they differed from those of his chief predecessor, Mr. E. H. Man—by so carrying it out as to lead the reader to suppose that Mr. Man's work was not worth much. Mr. Brown's defence is that in adopting his plan of procedure he was obeying the instructions of the Anthony Wilkins Studentship, under whose auspices his work was undertaken. The reviewer did not complain of the plan but of the method of carrying it out. Next, with regard to the reviewer's criticism of the unwisdom of adopting the *Anthropos* Alphabet of Pater Schmidt for his work in supersession of the long-established alphabet compiled by so competent an authority as Mr. A. J. Ellis, Mr. Brown writes that he has "no hesitation in accepting the *Anthropos* Alphabet as the nearest approach possible at the present time to a scientific universal alphabet." But at the same time he quotes the fact that Sir Richard Temple published a universal grammar which has not been adopted to any extent by other writers, "doubtless because of the objection they feel to giving up the system of grammar to which they are accustomed." Mr. Brown, having thus the fate of Sir Richard Temple's grammar before him and appreciating the reason for it, might have been warned of the fate awaiting the *Anthropos* Alphabet, and that the only result in the circumstances of partially adopting it in a work, which he himself says "does not deal with the languages of the Andamans," would be to puzzle, and not enlighten, the student. To the reviewer's criticism of use being made without acknowledgment of information gathered by living predecessors, Mr. Brown raises the defence that any passages bearing such an interpre-

tation must have occurred in the introduction "which was meant as such and nothing more" It certainly does not justify the "correction" of the work of highly experienced local officials with not only the people and the country before them, but also the possession of the official technical works and some of the other general books, on which Mr Brown relies for his facts

IN a book entitled "Science and Human Affairs," which Messrs George Bell and Sons, Ltd, will shortly publish, the author, Dr W C Curtis, will recount how the conveniences of daily life and the safeguards to health have been discovered, and the possible bearing of science on human affairs in the future

THE following catalogues, which should be useful to readers of NATURE, have just reached us: No 95 (of Botanical and Zoological Works) from Messrs Dulau and Co, Ltd, 34 Margaret Street, W 1, No 216 (of Periodicals, Collections, Transactions, and Publications of Learned Societies, etc) from Messrs W Heffer and Sons, Ltd, Cambridge, and No 372 (miscellaneous, including Natural and Physical Sciences) from Messrs Bernard Quaritch, Ltd, 11 Grafton Street, W 1

MESSRS LONGMANS AND CO have in preparation, in four volumes, "A Natural History of the Ducks," by Dr J C Phillips, of the Museum of Comparative Zoology, Cambridge, Mass, U S A, which will aim at giving an exact and detailed description of all known species of ducks, mapping their breeding and migration ranges It will also contain full life histories of the European and American species The work will be illustrated in colour and in black and white by F W Benson, A Brooks, and L A Fuertes Vol 1 is nearly ready for publication

SIR RONALD ROSS is bringing out, through Mr John Murray, a work entitled "The Great Malaria Problem and its Solution an Autobiographical Account," which will give a complete history of the discovery of the relation between malaria and mosquitoes, showing how malaria is carried from man to man Another book in the same publisher's announcement list is "Gardening for the XXth Century," by C Eley, in which attention is chiefly directed to the more permanent features in gardens The work will contain a list of selected trees and shrubs, with descriptive and cultural notes, and brief chapters upon botany and nomenclature

Our Astronomical Column.

MERCURY VISIBLE AS A MORNING STAR — Mercury will reach its greatest elongation, 18° 38′ west, in the early morning of October 31, and will be visible before sunrise during the period from about October 22 to November 10 The planet will rise about $1\frac{3}{4}$ hours before the sun, and should be easily visible about an hour before the times of sunrise Its position will be near the horizon in E by S, and it will shine with a rosy, fluctuating light about equal to that of a first magnitude star

The planet Saturn will be very near Mercury on about October 23, when the distance separating the two orbs will be a little more than 2°

Telescopic observations of Mercury are much required, the exact time of the planet's rotation being doubtful It is a good plan for those observers who do not possess equatorial telescopes to pick up the planet when it is visible to the naked eye, and to get and retain the disc in the field of view of the instrument until some time after sunrise, when it will have risen sufficiently high above the vapours near the horizon to permit the image to be well defined Mercury certainly presents dusky markings which are capable of being followed when clear weather allows, and the planet offers a much better prospect for successful scrutiny than Venus

COMETS —Perrine's periodic comet, 1896 VII and 1909 III, should now be looked for in the moon's absence The following ephemerides are on two assumptions of the time of perihelion

Date Greenwich Noon	Assumed T Oct 3 R A		Assumed T Oct 3 Decl	Assumed T, Oct 11 R A		Assumed T, Oct 11 Decl
	h	m		h	m	
Oct 19 0	7	45	19° 0 N	7	19	24° 0 N
27 0	8	5	14° 3	7	40	18° 7
Nov 4 0	8	21	9° 0	7	56	13° 4
12 0	8	33	5° 1 N	8	9	8° 1 N

Search should be made near the line joining the two positions for each date

Mr Wood sends the following elliptical orbit of comet 1922 *a*

EPOCH 1922, JAN 1·0

M	0° 2′ 1″
ω	183° 37′ 32″
Ω	274° 30′ 13″
i	32° 30′ 16″
log e	9·9953713
log a	·1871524
μ	1″·857

Period about 1900 years

Mr Wood is at work on a more exact orbit, using photographic positions that extend to April 25 last

THE MASSES OF VISUAL BINARY STARS —The *Astronomical Journal*, No 807, contains measures of the parallaxes of several binary stars made photographically at the Sproul Observatory by Messrs J A Miller and J H Pitman Investigation was made as to how far the irregularity of the combined image and the change in relative positions due to orbital motion between the exposures might introduce error The probable errors seem to be quite as small as for single stars The parallaxes deduced by other observers are tabulated as well as their own, and masses are deduced and classified according to spectral type with the following results for average mass B 4·91, A 3·10, F 3·02, G 1·77, K 1·57, M 0·65 Only two M stars were available

In conclusion, the advisability is pointed out of obtaining absolute parallaxes of as many binaries as possible by the relative shift of spectral lines due to different motion of the components in the line of sight The method has already been applied to Alpha Centauri and to Castor, also to Sirius (bright star only) A list is given of 18 stars to which the method might be applied, with the amount of present and maximum differential motion It is necessary either that both spectra should be visible or that the relative masses should be known

Research Items.

GYPSY FOLKLORE.—The new series of the Gypsy Lore Society's Journal is being actively conducted by its energetic secretary, Mr T. W. Thompson. The last issue (Third Series, vol. i, part 3) contains an excellent article by him on the Gypsy Grays as tale-tellers, which describes the methods by which the incidents of their stories are manipulated. This has a much wider interest than is implied by its title, and students of folk tales will find that it throws much needed light on the construction of these narratives.

HOCKEY IN ANCIENT GREECE.—An ancient Greek sculptured relief recently discovered in Athens, according to the *Times*, gives evidence that the Greeks played ball games other than with the hand. The relief represents six naked youths taking part in a game bearing every resemblance to modern hockey. The curved stick used may possibly supply an explanation of the singular curved object carved in relief on some of the votive offerings found at Sparta. These have been called "sickles." It is difficult to say why this implement should have been dedicated to Artemis, but the word "sickle" may have been the current slang for a boy's hockey-stick.

ROMAN REMAINS IN LONDON.—Recent excavations in the City have led to important discoveries. It seems to be proved that the ancient church of St. Peter's-upon-Cornhill was built inside of what was once a Roman fortress, which future investigation is expected to show was the first fortified camp of the Romans. If so, it is possible that it was built immediately after the re-establishment of order subsequent to the revolt of Boadicea. Mr. W. C. Edwards, the archæologist in charge of these investigations, believes that during the next ten years more Roman discoveries will probably be made in the City than have been made for centuries. The excavation recently struck what is probably the most ancient wall yet found in London. At one point it is 5 feet thick, and above the footings were courses of tiles, four abreast, each 13 inches broad. Rooms were added to it with plastered walls which appear to be of imitation alabaster, the wall being overlaid with a layer of white cement, almost as thin as paper, on which designs had been painted by a very skilful artist. It is now clear that Gracechurch Street was not Roman: it probably belongs to Saxon times, and was the work of Alfred the Great.

ARCHÆOLOGY IN PALESTINE.—Among the obligations undertaken by Great Britain in connexion with the control of Palestine is that of promoting archæological research. It was a condition of the scheme that in the Advisory Board for Archæology other nations should be represented. The first work which will now be undertaken is the excavation of the ancient City of David on Mount Ophel, immediately south of the existing walls of Jerusalem. Three different attempts have been made to probe the secrets of the hill, and though attended with some measure of success, practically the whole of Jebus, the original stronghold, the Palace and Millo of David, and in all probability the tombs of the Kings of Judah, await investigation. An area of ten acres has been preserved by the Administration, and this is now available for excavation. East of Jordan an immense field remains practically untouched, and many of these sites are of importance equal to that of Palestine itself. Especially at Jerash, the ancient Gerasa, there are wonderful remains of the Roman city, which show that it was one of the most imposing cities of the Roman period. The excavation of these Palestine sites is likely to throw welcome light not only on the history of the Hebrews but on the obscure annals of the nations who preceded them, and it may be hoped that the Palestine Exploration Fund, which counts among the names of its illustrious servants that of Kitchener, will receive adequate support in carrying out the well-arranged programme of investigation which is now laid before the scientific world.

UPPER CRETACEOUS GASTROPODS OF NEW ZEALAND.—Certain Upper Cretaceous gastropods of New Zealand, originally referred to Mr. H. Woods for description, were on his recommendation forwarded to Dr. O. Wilckens, then at Strasbourg, to deal with. The intervention of the war and consequent removal of Dr. Wilckens to Bonn delayed the completion of the task, and the finished monograph as rendered into English by the author himself has recently been issued as Palæontological Bulletin No. 9 by the Geological Survey Branch of the New Zealand Department of Mines. The major portion of the fossils studied are of Upper Senonian age. While these include a few species peculiar to New Zealand, resemblances can be traced in many examples to species from beds of equivalent age in North Germany, Chili, Patagonia, the Antarctic Regions, and South India. Of the indigenous forms the most striking is the remarkable *Conchothyra parasitica*, and Dr. Wilckens gives a very careful account of its strange growth and development. The plates accompanying the monograph are deserving of much praise, and there is a map showing the localities whence the fossils were obtained.

MARINE FOSSILS IN CENTRAL INDIA.—The General Report of the Geological Survey of India for 1921 contains a confirmation, and some further particulars, of the discovery of marine fossils in the lower Gondwana series of Central India, which was reported in some of the Indian newspapers about nine months ago. The discovery, which was made by Mr. K. P. Sinor, State Geologist to the Rewah Durbar, at Umaria, situated almost centrally in the broadest part of the Peninsula, consists of a shell band, about 3 inches thick, composed almost entirely of shells of the genus Productus. Below the shell band are quartz grits which pass up, through the band, conformably into sandstones of Lower Barakar age, the bed itself lying not far from the junction of the Gondwana rocks with the underlying gneiss, in beds which are usually regarded as of Talchir age. The discovery has been further investigated by Mr. P. N. Mukherji, field collector of the Survey, who added two specimens of Spiriferina to the fauna. The Productus has not yet been identified, but it is new to India; the Spiriferina is close to, and probably identical with, *S. cristata*, var. *octoplicata*. The fossils, therefore, are not of great assistance in determining the precise age of the band, but the discovery of marine conditions in the centre of the Peninsula, where no marine rocks of later than probably pre-Cambrian age had previously been found, is of great interest and importance. Dr. L. L. Fermor, the officiating director, by whom the report is made, discusses the question of whether the sea lay mainly to the north, or the west, of the newly discovered Productus locality. In either case the discovery, though of interest as marking a greater extension of the sea than had been previously suspected, does not materially alter the conclusion that the Indian Peninsula is a region which has been continuously dry land throughout the whole period covered by the sequence of fossiliferous rocks.

THE DISTRIBUTION OF TEMPERATURE IN SCANDINAVIA.—The Meteorological Institute of Sweden has published an important paper and series of charts by Mr. H. E. Hamberg on thermosynchrones and thermoisochrones in the Scandinavian peninsula (*Bihang till Meteorologiska Iakttagelser*, *Bd* 60, 1918 (1922)). In tables and charts, founded on the observations of 232 Swedish and 83 Norwegian stations, Mr Hamberg gives the mean annual dates at which certain temperatures reign. The temperatures are reduced to sea-level for this purpose, although Mr Hamberg fully realises that for certain geographical uses the value of the charts is thereby lessened, and he gives two pairs of charts, spring and autumn, one for 12° C. and the other for 0° C., in which the actual temperatures are utilised. A second series of charts indicates the average number of days with a temperature above or below certain figures. The curves on these charts Mr Hamberg terms thermoisochrones. The charts, which are small but very clear, are most useful for geographical purposes.

SPELL OF WARM WINTERS IN EUROPE.—The abnormal winter warmth recently experienced in Central Europe, embracing England, is dealt with in the *Meteorological Magazine* for September by Mr C. E. P. Brooks, of the Meteorological Office. A chart is given showing the differences of the mean temperatures for the winter, comprised by the months December, January, and February, for the years 1911 to 1920, and the long period averages for the combined winter months, mostly covering the years 1851 to 1910. At Budapest the winters of the past ten years have on the average been more than 4° F. warmer than the normal winter. At Zurich the excess is 2°·6 F., at Paris, 2°·1 F., and at Kew, 1°·8 F. On the Atlantic sea-board the winters of the decade in question have been slightly colder than the normal. There is no appreciable difference of temperature for the rest of the year, the summer months for the years 1911 to 1920 having been, on the whole, somewhat cooler than the average. The abnormal warmth of the winters was not confined to low levels; the mean winter temperature for the ten-year period at St Gothard, 6877 feet above sea-level, is 1°·9 F. above the normal. The author suggests a tentative explanation connecting the abnormal warmth with the general decrease of sunspot numbers since the nineteenth century. Taking the mean winter temperature at Greenwich for the ten-year period, 1911 to 1920, it is 1°·5 F. above the 60 years' average, and the mean was above the normal in 8 winters out of 10, the excess being more than 3° F. in 4 winters. In the ten-year period from 1886 to 1895 the mean winter temperature at Greenwich was 1°·9 F. below the normal for sixty years, and in 8 winters out of 10 the mean was below the average, the deficiency amounting to 3° F. or more in 3 winters; this is a different period from that given by the author and with an opposite effect.

GLARE FROM MOTOR HEADLIGHTS.—The descriptions of motor headlights exhibited at the meeting of the Optical Society on May 11 will be found in part 4 of volume 23 of the Transactions of the Society, together with a report of the discussion of the conditions which a satisfactory headlight should fulfil. In America these conditions are that 100 feet ahead of the car at a point 5 feet above the horizontal, the illumination must not exceed that due to a lamp of 750 candle power. The conditions laid down in this country by the Ministry of Transport relate to the width and height of the beam and place no restriction on its intensity. The reconciliation of the requirements of the driver and the pedestrian or driver he is approaching is difficult, but the general opinion of those who took part in the discussion appeared to be that the beam should have a candle power of 3000 in a direction half a degree below the horizontal and be reduced to 500 or 600 candle power in a direction one degree above the horizontal. As the glare effect is due to contrast, it was further suggested that the car body and the road at the side of the car should be illuminated to some extent as well as the road in front.

A NEW THEORY OF VISION.—A photo-electric theory of vision has recently been put forward by Dr F. Schanz of Dresden and has been discussed in the *Zeitschrift fur Augenheilkunde*. At present it is incomplete, but according to a paper in vol. 54 of the *Zeitschrift fur Sinnesphysiologie* the author hopes to fill in the gaps by work on which he is at present engaged. In outline it is as follows. Light on entering the eye is absorbed by the visual purple, which as a result emits electrons at speeds which depend on the wave-length but not on the intensity of the incident light; that is, the visual purple is photo-electric. The electrons impinge on the rods and cones and produce the sensation of light. If their velocities do not differ widely they are equalised during their passage to the rods and cones and produce a single sensation corresponding to the mean velocity; but if they differ materially the interval between their emission and their arrival at the rods and cones is not sufficient to equalise them and they produce distinct sensations. Over a range of wave-lengths of 1×10^{-5} cm equalisation is produced, but if all wave-lengths over a range double this are present, the sensation of white is produced, whether the range be *e.g.* from 4 to 6 or from 6 to 8×10^{-5} cm.

TESTING FOR VITAMINS.—Investigators are searching actively for some chemical means of recognising the presence of the vitamins in food materials, and the discovery of such a test would enormously increase the facility of research on these elusive substances. So far all the suggestions made have failed to withstand a critical examination. In a recent paper in the *Analyst*, Messrs. Drummond and Watson point out the close relation which exists between the presence of vitamin A in fats and the well-known reaction given by liver oils, which consists in the production of a purple coloration when the oil is dissolved in an organic solvent and a drop of sulphuric acid is added. All the liver oils of mammals, birds, and fish examined by the authors gave the reaction, but they also find that it is given, although less strongly, by the body fat of some animals and by butter. In striking agreement with the behaviour of vitamin A, the power of producing the coloration is lost when a current of air is passed through the fat at 100° C. but not when the fat is heated at this temperature in absence of air. Again, when the fat is hydrolysed it remains, with the vitamin A, in the unsaponifiable fraction. Moreover, the intensity of the reaction was found to be roughly proportional to the vitamin A content of a series of fish-liver oils. The livers and fat of pigs and rats fed on diets deficient in vitamin A did not give the reaction, but this reappeared when the deficiency was made good. It is obvious that there is a close parallel between the two properties, and the authors, without claiming that the test actually indicates the presence of the vitamin, suggest "that the association may be of some significance." The necessity for this caution is indicated by the facts that although the marine diatom Nitzschia has been shown to be rich in vitamin A the oil extracted from this organism did not give the purple colour test with sulphuric acid. A similar negative result was obtained with plankton oil, although the reaction was given by certain marine algæ.

Tendencies of Modern Physics.

THE Swiss Society of Natural Sciences met this year at Berne on August 24 to 27. The programme of the session comprised several discussions on questions of general interest, and papers of a more special character communicated to the various sections. The work was divided between the following sections: (1) Mathematics, (2) Physics, (3) Geophysics, Meteorology, and Astronomy, (4) Chemistry, (5) Geology, Mineralogy, and Petrography, (6) Botany, (7) Zoology, (8) Entomology, (9) Palæontology, (10) Anthropology and Ethnology, (11) Medical and Biological Science, (12) History of Medicine and Natural Science, (13) Veterinary Science, (14) Pharmacy, (15) Engineering History.

We cannot give here a detailed account of this annual event in Swiss science; we shall therefore confine ourselves to a résumé of the address of Prof. C. E. Guye, of Geneva, in opening the series of general discussions.

Taking the title, "The Tendencies of Modern Physics and the Conception of Matter," Prof. Guye first showed that modern physics was becoming more and more electromagnetic, discontinuous, and statistical. To these three characteristics, which have been sufficiently disconcerting to minds accustomed to the classical conceptions of the second half of the nineteenth century, there has now been added a fourth, of still more perplexing character, in the introduction of the principle of relativity. In adopting this principle physics has displayed a distinctly metaphysical tendency, which sometimes ventures to introduce into scientific discussion a dogmatic method of procedure. It is true that the difficulty is compensated by important advantages, resulting from the fact that the formulæ of relativity introduce more simplicity in the dynamics of very great velocities, and more unity between the various branches of physics.

After having shown how physics, like chemistry, has moved steadily along the path of discontinuity by the introduction of the atom of electricity and the theory of quanta, Prof. Guye spoke of the consequences of this discontinuity, which complicated greatly the explanation of phenomena apparently of the most simple character.

How, indeed, could one follow, by means of the equations of mechanics, the reciprocal actions of a nearly innumerable group of discontinuous elements (molecules, atoms, electrons)? This extreme complication which characterises the phenomenon, apparently so simple, when it is desired to study it intimately, led to the introduction of kinetic theories. The calculus of probabilities then came to the aid of physicists, powerless as they were to solve, by means of the equations of mechanics, the inextricable problems which were proposed to them. But the consequence of these kinetic theories is to lead us to conceive physico-chemical laws as statistical, so that we must picture physico-chemical determinism as a statistical determinism, to which the law of great numbers imparts all the appearance of infinite precision.

The progress of physics towards electromagnetism is particularly striking. The first decisive step along this path was made by Maxwell, to whom we owe the electromagnetic theory of light, which, universally accepted as it is to-day by physicists, unites in a systematic whole the phenomena of light and of electromagnetism. But this tendency to explain physical phenomena by the laws of electromagnetism has only served to make it still more accentuated. It has even attacked the mechanics which seemed to be the immutable basis of the old physics. To-day the fundamental postulate of mechanics—inertia—can be satisfactorily explained in terms of the properties of an electromagnetic field, and more and more intermolecular forces appear to be of electromagnetic nature (Debye, Keesom).

But the main reason for this constant evolution of physics towards electromagnetism is the work carried out particularly in England (Rutherford's school), which has exhibited it in a most convincing fashion. The material atom itself appears to be constituted entirely of charges of electricity, positive and negative (electrons), and all physical forces, with the exception of the mysterious force of gravitation, will thus be found, in the last resort, to be electric and magnetic forces.

In the second part of his address, Prof. Guye showed how the conception of matter, as defined by inertia, had evolved from Lavoisier to Einstein, and to the most recent work of Rutherford and Aston. Without committing ourselves positively to Prout's hypothesis, which would make the atomic weights of the elements integral multiples of that of a unique constituent—the atom of hydrogen—new developments point to a duality of ultimate material, the positive electron which is mainly responsible for the inertia of the atom, and the negative electron.

In short, the startling progress realised in physics during the last thirty years has reduced to naught all those fluid phantoms which we knew—imponderable electric and magnetic fluids; only the most tenacious among them—the aether—offers still a partial resistance.

Physicists have thus been led, little by little, to the idea of the materiality of electricity, and still more the formulæ of relativity point to the parallelism between inertia and energy, that is, to the fusion into a single principle of the two principles which govern all physical phenomena—the principle of the conservation of mass and that of the conservation of energy.

Such are the important results, not only from the scientific point of view, but also from that of our best philosophic culture, which modern research has brought forward during the course of the last thirty years.

The Isothermal Frontier of Ancient Cities.[1]

THE northern frontier of the Roman Empire is shown in atlases of ancient geography, and that of the Achæmenian Empire of the Persians and of the dynasties which succeeded in the Middle East. The frontier of the ancient Chinese Empire has not been made similarly familiar, and in place of it there is the representation of the Empire of China as it has been in mediæval and modern times. From this most of Manchuria, all Mongolia, and the Ili valley must be shorn off in order to get the Chinese northern frontier as it was under the Han dynasty in the beginning of the second century after Christ, the age of the Antonines in Europe. At this time, when the ancient civilisation of Eurasia was at the height of its culture and apparently at the maximum of its power, the northern frontier once controlled by

[1] Abstract of a paper by Dr Vaughan Cornish read before Section E (Geography) of the British Association at Hull on Sept. 12.

the Persian Achæmenidæ was divided between the Parthians, capitalled at Ctesiphon, and the Kushan dynasty of the Yue-chi, capitalled at Peshawar. These four northern frontiers, Roman, Parthian, Kushan, and Chinese, were consecutive, forming an unbroken line from the mouth of the Rhine near the modern Katwyk in Holland, 52° N., to the east coast of Korea in about 41° N. South of the line a vast array of established cities stretched for seven thousand miles across Eurasia, in some parts protected by natural barriers, in others defended by lines of masonry fortification. North of the line were the tents of nomads, huts of forest dwellers, and stockaded defences of earth and wood. In the northern part of modern Germany there were territories north of the line which the Romans had abandoned as untenable or unprofitable. South of the line in Eastern Europe was the district of Dacia which Augustus preferred not to touch, but Trajan was compelled to occupy. In this country the native people had in the interval begun to construct masonry fortifications.

In the course of an investigation of the geography of capital cities, it was found that this northern frontier of ancient cities, on the eve of the barbarian irruption, has, within narrow limits of variation, the same average temperature throughout. It is a true annual isotherm, not an isotherm reduced to sea level. Along the European part is a line of modern cities with meteorological observatories. The annual temperatures of eight of these, strung out along the length, has an average of 48°.6 F. Asia is not well off for meteorological records near the line on the south, and the second table consists of a list of towns mostly under Russian rule just north of the line where proper records have been kept. It will be observed, therefore, that their temperatures are rather lower than that along the frontier of the ancient cities. The average temperature of these eight towns north of the line is 47°.4 F. A very long gap in these towns occurs between Kuldja and Mukden, but the record for the Lukchun depression in Chinese Turkestan, a little south of the frontier yields a not inconsistent figure, if corrected for the general height of the surrounding country, and that of Peking is not discordant. Further east the generalised isotherm of 48°.5 F. reaches the eastern coast of Korea in about 41° N. (somewhat north of the peninsula portion of the country) which cannot be very far from the frontier of its ancient cities.

In the detached Roman possession of Britain the inner and principal line of fortification had its western terminal at Carlisle, where the temperature is 47°.8 F. Eastwards of the continent of Eurasia the conquest of the Japanese islands by their present masters was only completed at a much later date than that under consideration, but the Japanese derived their culture from ancient China (mainly through Korea) and it may therefore be significant that they were content to conquer, without colonising, Yezo, the northern island, and that what is reckoned by the Japanese as Japan proper, and is called by them "Old Japan," does not include Yezo but stops short with Honshiu, the mainland, and that the annual isotherm of 48°.5 F. traverses the strait of Tsugaru which separates Old Japan from Yezo.

The fact that the annual temperature along this immense line only varies within remarkably narrow limits cannot be reasonably contested. If it be the case that desiccation has occurred generally in Asia along this line since the second century of our era its probable effect would be to lessen the winter and raise the summer temperature, leaving the annual temperature much the same.

The coincidence of frontier and true isotherm is not a mere consequence of east and west barriers of mountains, inland seas, and rivers, for these had to be supplemented by long lines of fortification. Neither was it due to unsuitability of the southern country to pastoral peoples, for in Asia there was much coveted grazing land south of the settled frontier. Precisely how far this coincidence is significant it is yet difficult to say.

Annual Temperatures along the Frontier in Europe	°F.	Annual Temperatures north of the Frontier in Asia	°F.
Carlisle	47.8	Stavropol	47
Utrecht	47.8	Astrachan	50

The Mechanism of the Cochlea.

MOST medical students have probably felt that current physiological teaching provided them with only a hazy conception of the mechanism for hearing in the cochlea. Helmholtz put forward the view that this organ contained a series of resonators, which were differentiated like a set of piano strings, so that each string vibrated only in response to one particular note. It will be remembered that the cochlea forms a spiral, which when unwound consists of two chambers, placed one above the other, and separated by the basilar membrane. At one end (the base) of the cochlea, in the wall of the upper chamber, is the window which is set in vibration by the middle ear, while in the wall of the lower chamber is a similar window whose function is to prevent the pressure from changing inside the cochlea when the upper window moves. Both chambers contain fluid, and, at the other end (the apex) of the cochlea, the chambers unite, for the basilar membrane ceases just short of the apex.

The suggestion that the fibres of the basilar membrane can act as a resonating system has been current since it was pointed out that their length (measured across the canal) varied continuously from the base to the apex. Now the fibres of a resonating system must obey the laws which govern vibrating strings, so that n, the number of vibrations of a string per sec., $= \frac{1}{2l}\sqrt{\frac{t}{m}}$, where l is the length of a fibre, t is the tension, and m is the mass per unit length. Gray showed in 1900 that the tension of the fibres of the basilar membrane also varied from the base to the apex, for while the spiral ligament which attached the membrane to the outer wall of the cochlea was very dense near the base, it was, on the contrary, very slender near the apex. We know, therefore, that the fibres of the basilar membrane are differentiated for tension and length, so that the short fibres near the base are under high tension, and the long ones near the apex are under low tension. To complete the requirements of the formula for vibrating strings, it is only necessary to discover a system by which the fibres are differentiated for mass, which differentiation must, as the formula

demands, be applied so that the load on the fibres is small near the base, but large near the apex

A great difficulty in supposing that the basilar membrane represents a system of resonating strings is the fact that it is immersed in fluid. It is precisely this point which Dr. George Wilkinson, in a paper read before the Section of Physiology of the British Association at the recent Hull meeting, conceives to be, not a difficulty, but the key of the whole problem. He suggests that the differentiation of the fibres as to mass, or the "loading" of the fibres, is brought about by the fluid in the canals. When the fibres at any point of the membrane vibrate in response to an impulse from the middle ear, they will be loaded by the weight of a column of fluid proportional to the distance of the vibrating point from the *fenestra rotunda*, which is the window between the cochlea and the middle ear. The column of fluid between the window and the vibrating point will be least in the case of a point on the membrane near the base of the cochlea, and greatest in the case of a point near the apex.

So much for Dr. Wilkinson's theoretical conception. He has provided a convincing proof of his views in the shape of two very ingenious models. The first is a brass box divided horizontally into two like the cochlea unwound from its spiral. The partition which represents the basilar membrane consists of a series of parallel wires of phosphor-bronze soldered firmly in position, and covered with formalised gelatin. On this basilar membrane is scattered blue enamel powder. There is a *fenestra rotunda* and *ovalis* at one end of the box, respectively above and below the basilar membrane, the windows being formed in each case by a rubber disc. The box is filled with water and is completely closed. In his first model, Dr. Wilkinson has kept all his phosphor-bronze wires at the same tension and of the same length. Yet he finds that when he applies a vibrating tuning-fork to the rubber membrane, or *fenestra rotunda*, the powder on the basilar membrane takes up a definite position which varies with tuning-forks of different rates of vibration. Thus a 200 D.V. fork produces a localised resonant response at a distance 3·3 cm. from the proximal end of the scale, while a 400 D.V. fork produces such a response at a distance of 0·9 cm. If one makes use of the formula for vibrating strings and supposes that the differentiation in resonance is due to the different loading of the wires by the fluid according to the above hypothesis, then the point of resonance to the lower tone should be 4 times the distance from the windows compared with that for the upper tone. Actually we see that it is not 4 times, but is 3·3/0·9 = 3·6 times. A very striking agreement!

Here then is proof of Dr. Wilkinson's contention that a system of transverse fibres, immersed in a fluid as it is in the cochlea, is already, by reason of the position of the *fenestræ*, differentiated for resonance in regard to the effective mass of the fibres.

In his second model, which is larger, he has carried out a differentiation of his phosphor-bronze wires in respect of tension and length. The differentiation of tension is effected by attaching weights of different sizes to the ends of the individual wires; while the lighter weights are attached to the longer fibres near the "apex," the heavier weights are attached to the shorter fibres near the base. In this way he has attained a model which gives a localised resonant response over a range exceeding four octaves.

One may say in conclusion that Dr. Wilkinson has made a very considerable contribution to our knowledge of the mechanism of hearing, and has presented the first clear conception of how the cochlea can work.

British Association Research Committees.

RESEARCH committees to deal with the following subjects were appointed by the General Committee at the recent meeting of the British Association at Hull. The names given are those of the chairmen and secretaries of the committees.

SECTION A (MATHEMATICS AND PHYSICS).—Seismological investigations: Prof. H. H. Turner, Mr. J. J. Shaw. To assist work on the tides: Prof. H. Lamb, Dr. A. T. Doodson. Annual tables of constants and numerical data, chemical, physical, and technological: Sir Ernest Rutherford, Prof. A. W. Porter. Calculation of mathematical tables: Prof. J. W. Nicholson, Dr. J. R. Airey. Determination of gravity at sea: Prof. A. E. H. Love, Prof. W. G. Duffield. Investigation of the upper atmosphere: Sir Napier Shaw, Mr. C. J. P. Cave. To aid the work of establishing a solar observatory in Australia: Prof. H. H. Turner, Prof. W. G. Duffield.

SECTION B (CHEMISTRY).—Colloid chemistry and its industrial applications: Prof. F. G. Donnan, Dr. W. Clayton. Absorption spectra and chemical constitution of organic compounds: Prof. I. M. Heilbron, Prof. E. C. C. Baly.

SECTION C (GEOLOGY).—The Old Red Sandstone rocks of Kiltorcan, Ireland: Prof. Grenville Cole, Prof. T. Johnson. To excavate critical sections in the palæozoic rocks of England and Wales: Prof. W. W. Watts, Prof. W. G. Fearnsides. The collection, preservation, and systematic registration of photographs of geological interest: Prof. E. J. Garwood, Prof. S. H. Reynolds. To consider the preparation of a list of characteristic fossils: Prof. P. F. Kendall, Mr. H. C. Versey. To investigate the flora of lower carboniferous times as exemplified at a newly discovered locality at Gullane, Haddingtonshire: Dr. R. Kidston, Prof. W. T. Gordon. To investigate the stratigraphical sequence and palæontology of the Old Red Sandstone of the Bristol district: Mr. H. Bolton, Mr. F. S. Wallis.

SECTION D (ZOOLOGY).—To aid competent investigators selected by the committee to carry on definite pieces of work at the Zoological Station at Naples: Prof. E. S. Goodrich, Prof. J. H. Ashworth. To summon meetings in London or elsewhere for the consideration of matters affecting the interests of zoology, and to obtain by correspondence the opinion of zoologists on matters of a similar kind, with power to raise by subscription from each zoologist a sum of money for defraying current expenses of the organisation: Prof. S. J. Hickson, Dr. W. M. Tattersall. Zoological bibliography and publication: Prof. E. B. Poulton, Dr. F. A. Bather. Parthenogenesis: Prof. A. Meek, Mr. A. D. Peacock. To nominate competent naturalists to perform definite pieces of work at the Marine Laboratory, Plymouth: Prof. A. Dendy (*Chairman and Secretary*). Experiments in inheritance in silkworms: Prof. W. Bateson, Mrs. Merritt Hawkes. Experiments in inheritance of colour in Lepidoptera: Prof. W. Bateson (*Chairman and Secretary*).

SECTION E (GEOGRAPHY).—To consider the advisability of making a provisional population map of the British Isles, and to make recommendations as to the method of construction and reproduction: Mr. H. O. Beckit, Mr. F. Debenham.

SECTIONS E, L (GEOGRAPHY, EDUCATION).—To

formulate suggestions for a syllabus for the teaching of geography both to matriculation standard and in advanced courses; to report upon the present position of the geographical training of teachers, and to make recommendations thereon; and to report, as occasion arises, to Council, through the Organising Committee of Section E, upon the practical working of regulations issued by the Board of Education affecting the position of geography in training colleges and secondary schools. Prof T P. Nunn, Mr W. H Barker

SECTION G (ENGINEERING)—To report on certain of the more complex stress distributions in engineering materials Prof E G Coker (*Chairman*), Prof L N G Filon, and Prof A. Robertson (*Secretaries*)

SECTION H (ANTHROPOLOGY)—To report on the distribution of Bronze Age implements Prof J L Myres, Mr H J E Peake To conduct archæological investigations in Malta Prof J L Myres, Sir Arthur Keith To conduct explorations with the object of ascertaining the age of Stone Circles Sir Hercules Read, Mr. H Balfour To excavate early sites in Macedonia Sir William Ridgeway, Mr S. Casson To report on the classification and distribution of rude stone monuments Dr R R Marett, Prof H J Fleure The collection, preservation, and systematic registration of photographs of anthropological interest Sir Hercules Read, Mr E N Fallaize To conduct archæological and ethnological researches in Crete Dr D G Hogarth, Prof J L Myres To co-operate with local committees in excavation on Roman sites in Britain Sir William Ridgeway, Mr H J E Peake To report on the present state of knowledge of the ethnography and anthropology of the Near and Middle East Dr A C Haddon, Mr E N Fallaize To report on the present state of knowledge of the relation of early palæolithic implements to glacial deposits Mr H J E Peake, Mr E N Fallaize To investigate the lake villages in the neighbourhood of Glastonbury in connexion with a committee of the Somerset Archæological and Natural History Society Sir William Boyd Dawkins, Mr Willoughby Gardner To co-operate with a committee of the Royal Anthropological Institute in the exploration of caves in the Derbyshire district Sir William Boyd Dawkins, Mr G A. Garfitt To investigate processes of growth in children, with the view of discovering differences due to race and sex, and further to study racial differences in women Sir Arthur Keith, Prof H J Fleure To conduct excavations and prepare a survey of the Coldrum megalithic monument Sir Arthur Keith, Prof H J Fleure To report on the existence and distribution of long-barrows in the Isle of Man Prof H J Fleure, Dr Cyril Fox To report on proposals for an anthropological and archæological bibliography, with power to co-operate with other bodies Dr A C Haddon, Mr E N Fallaize To report on the best means of publishing a monograph by Dr Fox on the archæology of the Cambridge region Dr A C. Haddon, Mr H J E Peake

SECTION I (PHYSIOLOGY)—Efficiency of movement in men equipped with artificial limbs Prof E P. Cathcart, Prof A V Hill Muscular stiffness in relation to respiration Prof A. V Hill, Dr Ff Roberts.

SECTION J (PSYCHOLOGY)—The place of psychology in the medical curriculum Prof G Robertson, Dr W Brown Vocational tests: Dr C S. Myers, Dr G H. Miles

SECTION K (BOTANY)—To continue breeding experiments on Œnothera and other genera Dr A B. Rendle, Dr. R R Gates Primary botanical survey in Wales: Dr E. N. Miles Thomas, Prof. O V. Darbishire.

SECTION L (EDUCATIONAL SCIENCE).—Training in citizenship. Rt Rev J E C Welldon, Lady Shaw. To inquire into the practicability of an international auxiliary language Dr H Foster Morley, Dr. E H Tripp

University and Educational Intelligence.

BIRMINGHAM.—The University War Memorial, which was unveiled on Sunday, October 8, takes the form of three large panels of marble, on the eastern side of the entrance hall of the University, bearing the names of members of the University who fell in the war

The Muirhead lectures in social philosophy are to be delivered by Prof J H Muirhead, who has chosen as his subject "The Idea of Progress" The first of the series of seven is to be given on October 16 The lectures are free

CAMBRIDGE.—The Vice-Chancellor announces a legacy of 1000*l*, free of legacy duty, to the Agricultural Department of the University by the will of the late Charles Jewell, by the will of the late Dr Rivers books and pamphlets have been left to the library of St John's College, and in addition 70 volumes have been selected for the library of the Psychological Department and 295 volumes for that of the Department of Ethnology

Mr. W J H Sprott, Clare College, has been appointed demonstrator in experimental psychology

Mr J C Burkill and Mr A E Ingham have been elected Fellows of Trinity College

It is proposed to confer an honorary M A degree on Prof H R Dean

LEEDS.—At a Congregation of the University held on Tuesday, October 10, the Duke of Devonshire, Chancellor of the University, presiding, the following honorary degrees were conferred *Litt D* The Lord Bishop of Ripon (The Rt Rev Dr Thomas Banks Strong) and Mr Bruce Richmond, Editor of the *Times Literary Supplement* *D Sc* Sir Dugald Clerk, Sir Frank Dyson, Astronomer Royal, and Sir Richard Gregory, Editor of Nature, president of the Educational Section of the British Association, 1922 *LL D* Mr H I Bowring, Mr B Broadbent, Mr H McLaren, and Mr C F Tetley

Sir Dugald Clerk was presented by Prof Smithells, who said, "In him we welcome one who came to Leeds as a member of the first chemical staff of the Yorkshire College of Science, and he returns to-day a man eminent among his fellows as a great example of the ideal on which this University has spent so much of its early labours the harmonious and fruitful union of pure and applied science"

In presenting Sir Frank Dyson, Prof Whiddington referred to him as "the most distinguished British astronomer," who, they remembered with pride, is also a great Yorkshireman, and in his chosen field of work has been unvaryingly successful "Every one knows him as the Astronomer Royal, a position which in these days of astronomical discovery he has filled with the highest distinction"

Prof Smithells, in presenting Sir Richard Gregory, said "He stands as one of the most distinguished of those who strive to interpret science to the multitude, to obliterate the false antagonisms that have arisen between the different realms of knowledge, and to win for science her rightful place among the potent influences that act for the true enlightenment and progress of mankind"

LONDON.—Dr C Da Fano will begin on Wednesday, October 25, at King's College, at 4.30, a course of eight free public lectures on "The Histology of the

Nervous System." The subsequent lectures will be given on November 1, 8, 15, 22, 29, and December 6 and 13. No tickets are required.

Dr. George Senter and Mr. C. W. Crook have been elected by the science graduates to fill the two vacant seats on the Senate.

SHEFFIELD.—The Council has appointed Prof. A. H. Leahy to be emeritus-professor of mathematics, and Mr. R. Platt to be demonstrator in pathology and bacteriology.

DR. A. J. SUTTON PIPPARD has been appointed professor of engineering at the University College of South Wales and Monmouthshire, Cardiff.

THE Loughborough Technical College has since 1918 developed a well-equipped faculty of engineering with departments of mechanical and civil, of electrical, and of automobile engineering. In its calendar for 1922–23 (price 3s. 6d.) it claims that its own workshops enable it to provide the student with all necessary practical training concurrently with his theoretical work, thus obviating the risk, incidental to sandwich systems, of forgetting in the works what was learned in the college and *vice versa*. The college is said to have at present more than 1500 full-time day students in residence. The governors include representatives of the universities of Birmingham and Cambridge, as well as of Leicestershire County Council and Loughborough Town Council.

THE Merchant Venturers' Technical College of Bristol, in which is provided and maintained the Faculty of Engineering of the University of Bristol, has issued for the session 1922–23 a calendar (price 6d.) with 18 full-page illustrations. Like the Royal Technical College, Glasgow, it is in touch with a number of engineering firms which co-operate with it in regard to the training of apprentices, but, whereas the former arranges its engineering courses in such a way as to leave student-apprentices free to spend in their firms' works the summers intervening between the winter sessions of the college, a special feature of the Bristol "sandwich scheme" is that the student spends in the works 14 months between the first and second college (10-months) sessions. Among the free-tuition entrance scholarships of the Merchant Venturers' College is one "for the son of a citizen of Béthune who has passed either the B.-ès-L. or B.-ès-Sc. examination."

THE administration of schools in the smaller cities of the United States of America is dealt with in an interesting and stimulating way in Bulletin No. 2 of 1922 of the Bureau of Education (Govt. Printing Office, Washington, D.C., price 10 cents). The statistical basis consists of answers by 520 superintendents of education to a *questionnaire*. From the section relating to teachers' qualifications it appears that the standard requirements as regards training for teaching in elementary and in high schools respectively are two years of normal-school work for the former and four years of college work with professional courses for the latter. The United States Chamber of Commerce has lately, in a pamphlet entitled "Know and Help your Schools," given currency to the view that the work of the elementary school in forming habits and ideals being as important as the work of any other school division, the elementary school teachers should be as well trained and well paid as those of the high school, but it does not appear that many school boards have as yet adopted this view.

Calendar of Industrial Pioneers.

October 22, 1915. Sir Andrew Noble died.—Widely known for his important researches on guns, projectiles and explosives, Noble was born in Greenock on September 13, 1831, and for some years served in the Royal Artillery. Joining Armstrong in 1860, he was for many years director of the ordnance works at Elswick and after Armstrong's death became the head of the great armament firm. His original investigations cover a period of fifty years, many of his memoirs being contributed to the Royal Society.

October 24, 1903. Samson Fox died.—The founder in 1874 of the Leeds Forge Company, Fox patented in 1877 his well-known corrugated furnace for steam boilers, the adoption of which led to the use of higher steam pressures. He first made pressed steel frames for railway wagons and was a pioneer of the acetylene industry.

October 25, 1684. Dud Dudley was buried.—Born in 1599, Dudley was a natural son of Edward Sutton, fifth Baron Dudley. Educated at Balliol College, Oxford, he was summoned home to superintend his father's iron works in Worcestershire, and in 1619 took out a patent for the use of pit coal instead of charcoal for smelting iron ore, an improvement in iron manufacture successfully used by Abraham Darby at Coalbrookdale in 1735. Dudley served as a colonel under Charles I. His work, "Metallum Martis," was published in 1665.

October 25, 1903. Robert Henry Thurston died.—A pioneer in engineering education in America, Thurston was trained as an engineer under his father and served in the navy during the Civil War. In 1870 he became professor of mechanical engineering in Steven's Institute, where he organised the first engineering laboratory in the United States; in 1880 he became the first president of the American Society of Mechanical Engineers. Removing in 1887 to Sibley College, Cornell University, he greatly extended the courses of instruction and by the time of his death the number of students had increased from 60 to 960. He was well known as a scientific investigator, and for his contributions to thermodynamics, steam engineering, and the strength of materials.

October 28, 1899. Ottmar Mergenthaler died.—The inventor of the linotype machine, Mergenthaler, who was born in Wurtemberg on May 10, 1854, emigrated to America at the age of eighteen and worked as a watchmaker with his cousin in Washington. At Baltimore Mergenthaler came into contact with the reporter Clephane, and began work on a type printing machine which, after ten years and the expenditure of a million dollars, he at last brought to a successful issue. His linotype machine was first installed in 1886 in the composing room of the *New York Tribune*.

October 28, 1792. John Smeaton died.—The first "Civil Engineer" and the recognised father of his profession, Smeaton, like Watt, began life under an instrument maker in London. When in business for himself he gained a reputation by his scientific papers on wind power and other subjects. Though he constructed bridges and harbours he is known principally as the builder of the Eddystone lighthouse, an original work of great importance and utility which stood on the Eddystone rock from 1759 to 1882 and now forms a monument to Smeaton on the Hoe at Plymouth. Smeaton was a fellow of the Royal Society and in 1771 founded the Smeatonian Club for engineers.

Societies and Academies.

LONDON.

British Mycological Society (Keswick meeting), September 15-20.—F. T. **Brooks**: Some present-day aspects of mycology (presidential address). It is maintained that the fungi originated from protist organisms without direct relationship with the algæ, and developed upon novel lines as an entirely separate and characteristic group of plants. Arguments are advanced against the view that the fungi are phylogenetically related to the green and red algæ, or that they have been evolved from transmigrant seaweeds in ancient times. A monophyletic origin of the fungi is favoured. Most plant diseases are caused by fungi; hence there is need for closer co-operation between systematic mycologists and plant pathologists. Attention was directed to the inadequacy of the diagnosis of certain genera and species of pathogenic importance, and to the great influence of environmental conditions upon the growth of all kinds of fungal organisms. It is considered that mycologists and plant pathologists must be essentially botanists with the necessary fundamental training in chemistry and physics. For the plant pathologist a sense of crop values and of the important phases in the growth of crops should be inculcated.—Somerville **Hastings**: *Anellaria separata* growing in the Alps. The characters of these plants are related to the known conditions and compared with corresponding characters in phanerogams.—A. H. R. **Buller**: Luminosity in *Panus stypticus*. The mycelium and fruit body are both luminous, and by controlling the supply of oxygen the light can be turned on and off instantaneously. The light is given off even at or just below the freezing-point of water. Mycelium grown on wood blocks remained luminous for six months.—Miss E. M. **Wakefield**: Fungus-hunting in the West Indies. Observations were taken during six months spent in the Lesser Antilles and Trinidad. The characteristics of the fungus flora of these islands illustrate the distribution of fungi as affected by climate and the differences between tropical and temperate fungus floras in general.—Carleton **Rea**: Edible fungi, qualities from a gastronomic point of view of a number of the larger fungi.—M. C. **Potter**: Wart disease of potatoes. Preliminary experiments appear to indicate that the disease does not develop if the soil is rendered sufficiently alkaline (approximately P_H 10.5).

MANCHESTER.

Literary and Philosophical Society, October 3.—Mr. T. A. Coward, president, in the chair.—T. A. **Coward**: Manchester birds, 1822-1922 (presidential address). One hundred years ago, 1822, John Blackwall, famous for his monograph on "British Spiders," read before this society a paper on "periodical" birds observed in the neighbourhood of Manchester. This list was enlarged by him in his "Researches in Zoology," and the dates of observation extended from 1814 to 1828 inclusive. Blackwall also published a list of singing-birds, and of rare visitors, and contributed to various journals notes on the habits of birds. His works prove that the local avifauna has changed but little in spite of the great increase of population and the extension of the city boundaries. A few species have vanished, others have appeared and colonised, and though few birds can now be seen in Ardwick "fields" the same species which used to occur may be met with in the parks or on the outskirts of the populated areas. The possession of open spaces, and the protection afforded by the city authorities to birds in the parks, have saved many birds from local extinction.

MELBOURNE.

Royal Society of Victoria, July 13.—Mr. Wisewould in the chair.—H. B. **Williamson**: Revision of the genus Pultenæa. Pt. III. Six new species are described: *P. Boormanii* from N.S.W., *P. Kenneyi* (Q.), *P. teretifolia* (S.A.), and three from Victoria—*P. D'Altonii*, *P. prolifera*, and *P. Readeriana*. A number of new varieties are discussed.—W. M. **Bale**: Two new species of Bryozoa: *Catenicella Matthewsi*: nearly allied to *C. alata* and *C. carinata*, differs from all known species in having the alæ throughout uncalcified, perfectly hyaline, and apparently structureless. Alæ wide, fenestræ about 12-14, small, with converging fissures. Avicularia minute, on long arm-like processes. According to Levinsen's system a Pterocella. *Claviporella Goldsteini*: very close to *C. aurita*, but without the large elliptic suboral pore. Fenestræ 3, minute but distinct, with well-marked fissures. This character distinguishes it from *C. imperforata* and *C. aurita*. (The same as *Catenicella McCoyi* Goldstein, *nomen nudum*, Jelly's "Synonymic Catalogue").—E. F. J. **Love**: Gravity determinations in Australia. By comparison of all existing material, very precise determinations of gravity for Melbourne and Sydney observatories have been obtained. Helmert's new theory of the figure of the earth—according to which the equator is slightly elliptical instead of truly circular—reconciles in great measure the observed and theoretical values of gravity at the Australian stations; there is a possible correlation between gravity at a station and the geological age of the neighbouring strata.

WASHINGTON.

National Academy of Sciences (Proc., vol. 8, No. 9, September 1922).—P. **Franklin**: The meaning of rotation in the special theory of relativity. Newtonian equations for rotation can be used to express first approximations for points near the axis of rotation. Making certain assumptions, it is shown that the spacial geometry for the rotating system depends on the time and space co-ordinates of the point considered, and that the curvature of the spatial cross-section at any space-time point in its "natural" co-ordinates is the square of the angular velocity in radians per light-second.—J. A. **Eldridge**: Energy losses accompanying ionisation and resonance in mercury vapour. Electrons emitted from an oxide-coated cathode traverse a region of constant potential in the experimental tube, suffering collisions with mercury vapour; they pass through two diaphragms, each pierced by a single hole, to the receiving electrode in the lower end of the tube, which is freed from mercury vapour by liquid air. A retarding potential is applied to the receiving electrode. The current is plotted against the retarding potential and it is shown that, at voltages above the ionisation point, the most important type of resonance collision involves an energy loss of 6·7 volts and also that a collision involving an energy loss of 5·7 volts occurs in mercury. In an ionising collision, the impinging electron apparently loses all its energy, and the electron produced leaves the parent atom with negligible energy.—L. W. **McKeehan**: Crystal structure of beryllium and beryllium oxide. Beryllium in the form of a loosely packed powder in a pyrex glass tube was submitted to X-rays from a molybdenum target. The oxide was treated similarly to detect lines due to oxide present as impurity. The fundamental space lattice for both element and oxide was found to be hexagonal.—J. P. **Minton**: Some cases of nerve-deafness and their bearing on resonance theories of audition. Curves are plotted

showing the relative receiver current in the testing apparatus necessary for the threshold of audition at various pitches. It is found that unless the nerve endings or the nerves are destroyed, hearing is normal if the tones are sufficiently intense The internal ear mechanism lowers the threshold of audition but mechanical resonance of this structure is not responsible for tone perception —C **Lundsgaard** and D D **Van Slyke** The quantitative influences of certain factors involved in the production of cyanosis Cyanosis depends on the mean concentration of reduced hæmoglobin in the blood It is shown mathematically that 40 per cent of venous blood must be mixed with arterial blood to obtain the necessary concentration of reduced hæmoglobin Cyanosis usually becomes perceptible when this concentration is 5 gms per 100 c c of blood, but various influences may cause it to vary from 4-6 gms per 100 c c of blood

Acoustic Research.

THE work of men of science has laid the foundation for a great many improvements in the technique of building, and this is, perhaps, most directly evident in the domain of physics. The utilisation of energy in the forms of heat and electricity form striking examples, but little has been done in this country in connexion with the control of sound. This is somewhat curious since in the late Lord Rayleigh we possessed one of the greatest exponents of acoustics. With the present-day congestion of our towns, which seems to be an inevitable factor in the progress of civilisation, the reduction of noise becomes of constantly increasing importance and the present financial loss due to this cause must be very great, though probably impossible to estimate. Need also exists for investigation on the most efficient means of propagating sound in order to secure its most effective transmission and reflection.

The production of an acoustically successful auditorium is frequently of paramount importance in connexion with architectural design. Many of our public buildings erected by eminent architects show considerable faults in this direction, and as we may assume that these faults are not due to professional apathy, it would seem that the laws regulating the production of a successful building for hearing and speaking have yet to be worked out.

Unfortunately, the variations in the factors which have to be considered are many, and no two designs are wholly identical. Some opinions on this subject have recently been stated in the public press in connexion with the hall of the London County Council building, and the views expressed suggest that men of science are agreed that there is work to be done, and also need for work already done to be reduced to a form capable of absorption by the designer and constructor. Sir William Pope considers that quite a small expenditure of time and money would suffice to provide knowledge enough to enable an architect to render every hall acoustically perfect, but this view is evidently not shared by Sir Joseph Larmor, and others will be found who regard the subject as less easy of solution than might appear from the consideration of simple cases only.

Nor is the acoustic efficiency of public halls by any means the conclusion of the whole matter. There are more numerous cases in which the direct absorption of sound is of as great importance as is transmission in auditoria. In the hospital ward, the private sick-room, and in the office, where quiet and ventilation are so often incompatible, the best means of destroying unwanted sounds calls for scientific investigation.

That architects are not entirely indifferent to this subject is shown by the fact that on the formation of the Department of Scientific and Industrial Research several years ago, the Royal Institute of British Architects formally directed attention to the need for acoustic experiments, associated with design and construction.

This need is recognised elsewhere, as is evidenced by the work done in America where, at Geneva, Illinois, in the laboratory of acoustics built for the late Prof. Sabine by Col. Fabyan, much valuable research has been carried out. Before his death in 1919 at the age of fifty, Prof. Sabine had collected a great deal of experimental data on sound in relation to materials, and his researches had sufficiently impressed themselves on American architects more than twenty years ago to result in consultations on acoustic design. The laboratory is now under the direction of Prof. Paul E. Sabine, some of whose recent researches are referred to elsewhere in this issue with a brief description of his laboratory. In this building, devoted solely to acoustic problems, the difficulties of adequate sound transmission and suppression are constantly being investigated. Work of this nature must eventually prove a valuable national asset by preventing wasted effort and expenditure, and the example of America is worth serious consideration in this country.

There are a great many problems in which the work of the man of science can materially assist the architect, not only in acoustics but also in the use of materials for construction generally, but if science is to have its due appreciation it must supply information of a practical and simple kind which will appeal to workers in a field already so wide that they have little time for the study of theory, however interesting.

The Body Temperature of Birds.

A Study of the Body Temperature of Birds. By Alexander Wetmore Smithsonian Miscellaneous Collections, Vol. 72, Number 12. (Washington, D.C., U.S.A.: Smithsonian Institution.)

WITH regard to body temperature, animals are divided into two great groups, namely, warm-blooded and cold-blooded, the former including mammals and birds, the latter reptiles, amphibians, fishes, and all invertebrates. A more accurate distinction than the actual temperature, however, is based on the fact that the so-called warm-blooded animals have a constant temperature (homoiothermal) while the cold-blooded animals have a variable temperature which is practically the same as that of the environment in which they live (poikilothermal).

The essential difference between these two groups is, that homoiothermal animals—mammals and birds—possess a heat-regulating mechanism by means of which the heat production and heat loss are so balanced that the body temperature remains practically constant, while poikilothermal animals—all others, except mammals and birds—possess no such mechanism.

Although much time and research have been devoted by a host of investigators to the study of body temperature and heat production in mammals, comparatively little attention has been given to this field in avian physiology, and all interested in this much-neglected subject will be greatly indebted to the author of the above monograph for his important and valuable contribution.

The investigation covered a period extending from January 1912 to October 1919, and records were obtained from 1558 individuals of 327 species of birds distributed among 50 families. It was carried on within the limits of the United States of America, and all the year round, in temperate regions where the extreme cold of winter is not encountered. In addition to the 327 species examined by the author personally, the previously published records from 89 others are given in the form of a supplementary table, so that definite statements may be found in the work regarding the body temperature of 416 species of birds. A table giving the individual records in detail, not included because of the high cost of printing, is deposited in the files of the Smithsonian Institution of Washington, and may be consulted by those interested.

Specially constructed thermometers of the clinical type but with a wider range—95° F.+to 115° F+—were used. When a bird was shot a temperature reading was taken from the large intestine reached through the anus or from the proventriculus through the mouth, only when the specimen could be secured immediately. If there was any delay in retrieving a correct reading could not be made, so that it was only possible to secure records from less than half the birds collected. In the short time that intervened between the shooting and introduction of the thermometer, it is assumed that no appreciable loss of heat from the body took place, and that the figure recorded indicates the temperature immediately before death.

With regard to the diurnal rhythm of body temperature found in all homoiothermal animals, including man, the author was able to corroborate the work of previous observers, and it is particularly interesting to note that in nocturnal birds, such as owls, the normal rhythm is reversed, the temperature being highest during the night (period of activity) and lowest during the day (period of rest).

Hilden and Stenback found that by imposing an

artificial night (period of darkness) and day (period of artificial illumination) on birds confined in a darkened room the temperature rhythm was altered. After the second day the diurnal birds adapted themselves to the changed conditions so that the maximum temperature occurred at night and the minimum during the day. When the experiment was ended and birds again led a normal life in relation to daylight, the diurnal rhythm quickly returned. A similar change of rhythm has been produced artificially in the monkey. This bears on the question as to the cause of the diurnal temperature rhythm in animals. Some believe that there exists in the body a fixed periodicity of which the temperature rhythm is an expression, and that this periodicity persists under all conditions, and is, to a large extent, independent of outside influences. Others are inclined to question the existence of this mysterious periodicity, and look upon the diurnal variation as being due entirely to the action on the body of the various outside influences which affect body temperature, notably, muscular activity and sleep. The fact that the rhythm may be altered by changing the daily routine appears to give support to the latter view.

Although a distinct diurnal body temperature rhythm is found in birds with a wider range in many cases than in mammals, there is little evidence of a seasonal variation. This is all the more interesting, since no class of non-hibernating homoiothermal animals show greater evidence of cyclical bodily changes than do birds. During moulting time, in the late summer and autumn, they shed their feathers and show other signs of depressed vitality, while in the spring, in preparation for the mating and breeding seasons, they put on fresh plumage and become extremely active. However, heat production if not greatly increased in a short time, has no relation to body temperature.

As in the case of mammals, the temperature of the female was found to be slightly higher than that of the male of the same species and under the same conditions, in most cases, but in certain groups the opposite was found. For example, in the herons (Ardeidæ), in three species we have the following averages. Great blue heron (*Ardea herodias*), male, 104°·8 F., female, 103°·7 F. snowy heron (*Egretta candidissima*), male, 104°·8 F., female, 104°·0 F.; and the black-crowned night heron (*Nycticorax nævius*), male, 103°·5 F., female, 102°·6 F. Here there is a very pronounced difference in favour of the male, and the same is found in certain other shore birds.

Among other factors that influence the body temperature of birds it was observed that large masses of food, if cold, will frequently cause a sudden fall in temperature in a bird of small size, while bathing may produce a slight fall.

As in the case of mammals, nestlings and immature birds show a lower temperature and a wider variation than adults, due to the fact that the temperature control is less perfect. In a black-necked stilt (*Himantopus mexicanus*), one day old, a temperature as low as 95°·3 F. was recorded. Apparently this applies only to species with altricial offspring; it is not found in birds with precocial young, where the mechanism of temperature control is well organised at birth.

In considering the method of temperature control in birds, Mr. Wetmore believes with Soum, that the air-spaces play an important rôle in the regulation of heat loss. On account of the feather covering and the absence of cutaneous glands, little heat is lost by radiation and evaporation from the skin. This throws an increased burden on the respiratory system, supplemented by the ostial spaces, and the regulation of heat loss through this channel is the chief factor in avian temperature control. The author brings forward some first-hand evidence in favour of this belief.

Discussing the significance of temperature control in general, the statement is made that "In the bird, the regulation of body temperature has reached its highest point, though birds stand second to mammals from an evolutionary point of view. Proof of this is found in the fact that birds have the highest body temperatures known, and that none of them hibernate." This conclusion scarcely seems justifiable on the evidence at hand. The degree of heat control of any species is not to be measured by the actual height of the body temperature, but rather by its diurnal variation, and according to this standard the regulation of body temperature appears to have reached its highest point in *Homo sapiens*, since the diurnal range in him is less than in any other so-called homoiothermal animal so far investigated, although the actual body temperature is among the lowest for mammals and far below that of any of the birds.

It is generally held that the higher the bird in the zoological scale, the greater is the body temperature. The author agrees with this statement, as a rule, but points out many discrepancies. If the appended tables be examined it will be noticed that, when arranged by families, the highest temperatures are found in pigeons, cuckoos, woodpeckers, and in the great passerine order beginning with the Tyrannidæ and ending with the Turdidæ. In five species of the former the average body temperature for male or female was 110° F. or more. The highest average temperature for both sexes was found in the western pewee (*Myiochanes richardsoni*) with a mean of 110°·2 F., the greatest single individual reading being 112°·7 F. Contrary to popular belief,

it was found that the swallows, as a group, possess the lowest average body temperature. In seven species examined in this family one alone, the rough-winged swallow (*Stelgidopteryx serripennis*), showed an average greater than 107°·5 F. Humming birds also, "with their tiny bodies seem to have a considerable range in temperature, but as a whole fall low in body warmth."

The volume is an important monograph containing much valuable data, and it is a noteworthy contribution to this field of avian physiology.

The Romanes Lecture, 1922. The Theory of Relativity and its Influence on Scientific Thought. Delivered in the Sheldonian Theatre, May 24, 1922. By Prof. A. S. Eddington. Pp. 32. (Oxford: Clarendon Press, 1922.) 2s. net.

ANOTHER collection of books and pamphlets reminds us of the hold which the theory of relativity has on the public imagination.

The Abbé Moreux gives his book the title "Pour comprendre Einstein," though he seems to consider that the effort to understand him is so much waste of time, for in his view the theory is both superfluous and misleading. Dr. Strasser, an anatomist with an amateur's interest in physics, gives us a critical discussion of the theory, but it is manifest that he has not come near to understanding it. Prof. Rougier, a philosopher who has read all about the new physics, sets out to tell us something of the influence of the theory upon philosophy, but leaves us with the impression of a shallow and ill-digested understanding of the development of physical science, and tells us little about philosophy. Prof. du Pasquier and Dr. L. Bloch are less ambitious in their aims; they are content to be expositors and not critics. The results are correspondingly more successful and will probably be very useful to the French reader.

But among the books before us, the English reader naturally turns to Prof. Eddington's Romanes Lecture to hear the latest thoughts of one who has done more than any man living to establish and to popularise the general theory of relativity.

The lecturer impresses it upon his audience that it is stale news that the events around us form a world of four dimensions. There is, however, something that is new. It used to be customary for us to think of this four dimensional world as having a definite set of sections, any one of which represented the state of the universe at a particular moment of absolute time, the whole being thus stratified in recognisable layers. But now this stratification has disappeared, there are no absolute time sections: it is only the individual observer who, to meet his own convenience, dissects the whole into "rashers," labelling each with the mark of an instant of his own consciousness. With a wealth of illustration and with language both grave and gay Prof. Eddington seeks to cure us of our egoistic outlook, and to persuade us to the wider view which finds truth, not in a particular picture of reality seen from one angle, but in a vision which includes and comprehends every possible picture. "It is only in this undissected combination of four dimensions that the experiences of all observers meet." On this we need scarcely dwell here, save to remind ourselves that the fault from which he would save us is one to which men in all ages have been prone, and not the least sinners have been those whose profession was the pursuit of exact truth. Yet we cannot help feeling that at times the preacher goes too far and so damages his case. To quote an illustration from the lecture: We allow an apple to fall. The moment the apple is released the earth begins to rush up to meet it. This is "the apple's view of things." "It is simpler than Newton's. We should regard it as on an equal footing with that of a terrestrial observer." This is very like asking an engine-driver to admit that it is quite natural to consider that when he admits the steam to the cylinder he sets not the engine but the whole universe in motion.

This is trifling however. Let us return to our destratified world of four dimensions. If we have been able to achieve this vision or to conceive of its possibility, we have grasped the essence of the doctrine of relativity, and we have come near to a superhuman view of history. The world is laid out before us as a changeless whole. Time and space are no more.

All is static. Dynamics has been resolved away. We can no longer ask about causes; that is to go back to the human point of view. We can simply gaze upon the scene and seek to catch some of its salient features.

So far as our present conceptions go, one of the most striking things about the picture will be that it is fibrous. The tangible part of it will be a great number of threads, one-dimensionalities. These represent electrons. Mere mortals think of them as moving points, but with our new vision we see them as continuous threads. These are chiefly present in bundles, twisted together into ropes; what are these? They are the material bodies of the mortals. One is an atom. Another, much more complex, is a man; another is a chair. The former in one part is gathering more threads to itself; in another part the threads unravel and dissipate. Such is life. In one part the chair-rope and the man-rope are in contact; the man is sitting on the chair. But of the behaviour of man as mortal the picture tells us little. We must become mortal and see only sections of the picture before we can see him as a living being with an unfolding consciousness. If the poet and the mystic do indeed aspire to free themselves from the fetters of time and space, as we read in the concluding passage of the lecture, we fear that they will find but little left either of poetry or of mystery in the world after which they yearn.

But, leaving the poet aside, and returning to the physicist, what is left for him in the great synthesis of all science into the one map of all events? What becomes of his vocation of measurement? As Prof. Eddington emphasises again and again, he too, with all his experiments, is in the picture. His rules, scales, clocks, photographic plates are all there, their whole history is depicted. All his experiments of measurement are represented by the passage through the picture of the threads that represent the marks on the scales, meeting and intersecting the threads that represent other particles of matter. The four-dimensional picture itself is not to be measured. It contains within itself the process of measurement in the ordinary three-dimensional world and all the results are recorded for us to read. We have no four-dimensional scale which we may move about and apply to different parts of the picture for the sake of comparison. We merely stand, look, and try to read what we see.

Perhaps Prof. Eddington does not see the picture quite in this way. Perhaps the "world" for him is a four-dimensional continuum in which our threads are merely lines of singularity. He seems to contemplate as "measurable" the intervals between pairs of points in this continuum which do not correspond to events in the history of any particle or electron in the material universe. But we wish to ask him how these intervals are in practice to be measured. He says, "When we have mastered the geometry of the world we shall have inevitably learnt the mechanics of it." That is so. A complete description of the world lines of all particles necessarily tells us all about the phenomena of motion.

But to master the geometry of the world means to describe its main features by means of a few simple propositions. In Prof. Eddington's view, the process consists in measuring all the intervals between all pairs of neighbouring events, and then in examining whether these intervals will fit together in an Euclidean fashion, or in a particular type of non-Euclidean scheme. If we discover that they will fit in a recognised and manageable mathematical scheme, we have mastered the geometry of the world.

But we ask again how are these intervals to be measured. Since all measurements are contained in the picture, and since for the description of the picture event by event no system of intervals is necessary, the whole of our experimental measurements have nothing at all to do with a scheme of intervals, and any geometrical system whatever may be used for the purpose of attaching intervals. What, then, is it which discriminates between Einstein's system and any other possible one? It is simply this, that if we adopt that system, the facts of the motions of particles or of the propagation of light can be expressed in a very simple form. The path of Mercury, for instance, is a geodesic. Possibly this fact may be further analysed and shown to follow from the configuration of the electron being spherical. But in any case we cannot measure the tube which would represent such an electron in the super-world of four dimensions.

Thus Einstein's law of gravitation, by itself, is not a statement about the world at all. It is only when it is taken in conjunction with some other hypotheses, such as that the path of a particle is a geodesic, that it predicts anything, and becomes capable of experimental test. The world itself cannot be said to be either Euclidean or non-Euclidean, for it does not furnish us with definite values for the intervals between all pairs of events in the continuum. We may say that the world-phenomena are more simply described on the basis of a non-Euclidean system than on a Euclidean system; but it is surely not allowable to go further and say that this is "because the world is not a Euclidean or flat world." Prof. Eddington would perhaps reply that for him the world is nothing more than the measurements that we make of it, and that these measurements do not fit in a Euclidean scheme. But this brings us round again to the same question, what is meant by measurements of the four-dimensional whole? We would ask our lecturer to give us a sequel

S 1

to this discourse in which, assuming the four-dimensional presentation, he would state explicitly, either in general terms or by precise illustration, how he would compare the intervals between any two pairs of events.

E. CUNNINGHAM

The Marketing of Whole Milk.

The Marketing of Whole Milk By Dr H. E Erdman. (The Citizen's Library Marketing Series) Pp. xvi+333 (New York The Macmillan Company; London Macmillan and Co, Ltd, 1921) 21s net.

THE recent disputes concerning the price of milk have again shown how difficult the problem has become under modern conditions, more especially in the large towns The farmer is no longer able to take his milk direct to the consumer except in the case of a village or small town, and there has arisen a class of dealers or distributors who occupy the place of the middleman Some of these distributors are large companies with the command of much capital, and their powerful organisations have led to something very like monopoly The producers, on the other hand, have also organised themselves, and a struggle between the two parties has recently ended In the volume under notice, this question as it appears in the United States is very completely analysed, and Prof Erdman, who is an economist, has dealt with it more fully and critically than has previously been attempted After discussing the peculiar position occupied by milk as a foodstuff, and the regulations which the public health authorities of all civilised countries have imposed, the author takes marketing and distribution, instances what has been done in the past and states the present position The part played by the middleman and dealer is made clear, and the rise of collective bargaining is illustrated by the action of the Orange County farmers in their successful fight with the New York dealers in 1883, which may be regarded as the beginning of what has now become the general practice in the large American cities The strike—or better the boycott has been the weapon of the producers, and experience has shown that it is two-edged, owing to the difficulty which the farmer has in disposing of his milk—a perishable commodity—except by making it into cheese or butter or, at worst, by feeding it to stock, all of which courses are seldom remunerative It is made clear that the producers must also submit to regulations governing their combined action, otherwise the results are doomed to failure.

Other matters dealt with are the difficulty of arriving at the cost of milk, owing to the position of the farm, the ability of the farmer, the proximity to market, and so on, and it is laid down that the method of arriving at a basic price can only be a starting-point in negotiations.

This book, which makes a strong appeal to the general reader, will be of interest to all concerned in the milk trade, whether as producers, distributors, or consumers, and it should lead to what the author regards as the only solution of the difficulty—"a better understanding all round"

Our Bookshelf.

Proceedings of the London Mathematical Society. Second Series Vol 20. Pp. liv+502. (London: F. Hodgson, 1922) n.p

THE present volume of the London Mathematical Society's Proceedings is the fifty-fifth issued since the foundation of the society and the twentieth in the present (large octavo) series. Like the preceding volumes issued by the society, it consists mainly of papers which embody original investigations on various mathematical subjects. Many of the papers, of which there are nearly forty, will appeal only to a limited class of reader In mathematics, even more than in other sciences, the results of new investigations are apt to appear abstruse to the lay mind. The solution of a cubic equation, the Newtonian theory of gravitation, even the elementary applications of the calculus, fundamental and well known as they are now, were not familiar to the world, or even to the general run of university students, for many years after their discovery By providing facilities for the publication of these specialised researches the London Mathematical Society has earned the deep obligation of the English mathematical world Practically all the society's income is expended in producing its Proceedings, and, in view of the increased cost of printing, a large membership is essential to provide adequate funds Inasmuch as every man is a debtor to his profession, every English mathematician should help to further the work of the society by becoming a member

In the volume under review the articles most likely to appeal to the general reader are the excellent obituary notices of the late Lord Rayleigh and Herr Adolf Hurwitz, written by Profs. Lamb and Young respectively. There is also printed a presidential address on "Some Problems in Wireless Telegraphy" by Prof Macdonald. Of the more technical papers it would be invidious to single out any one for special mention The society insists on a high standard of excellence in everything it prints, and the inclusion of a paper in the Proceedings is a sufficient guarantee of quality. We notice that there is an almost entire absence of pure geometry from the present volume. Can it be that research in this subject is no longer encouraged in England?

The method of indexing each individual volume of the Proceedings leaves nothing to be desired. A subject index to the first thirty volumes of the first series was issued many years ago. We suggest that the time is approaching when the Council should consider the desirability of publishing a further subject index to the later volumes. W. E. H. B.

A Laboratory Manual for Comparative Vertebrate Anatomy. By Libbie H. Hyman. Pp. xv + 380. (Chicago: University of Chicago Press, 1922.) 2.50 dollars net.

THIS work is the outcome of a particular course of practical lessons conducted by its author. The disability which such an origin fastens upon a book is well known to every teacher of zoology, and Mr. Hyman's book is no exception to the rule. It suffers from the conditions of its birth—not that these, though American, were insalubrious, but that they were so highly specialised as to limit greatly the adaptability of the offspring. Nevertheless the care that has obviously been taken by the author, and his ability in presentation, should make his book useful even in our small cis-Atlantic schools of zoology, where a somewhat more elastic course of instruction is possible than that provided at Chicago.

Mr. Hyman rebels against the tyranny of the type system, and uses the comparative method of study in his laboratory. His chapters describe in succession the systems of organs of the Vertebrata as exemplified by Elasmobranchs (Mustelus, Acanthias, Raja), Urodeles (Necturus), a Chelonian, the pigeon, the cat, and the rabbit. The instructions for dissection are clear and sufficient, and an attempt is made to bridge the gulf which commonly yawns between the principles of the lecture room and the observations of the laboratory, by supplying an accompaniment of morphological comment in the form of introductions and summaries to the chapters. This device and the general nature of the first four chapters disguise—but do not dispose of—the evils of the type system, which are perpetuated in spite of the author's dismemberment of his types and the wide dispersal of their remains throughout the book.

Only one notable omission has been detected. Mr. Hyman's classification of the Chordates—two pages in length—ignores the Dipnoan fishes, nor in the whole of his book do they once appear, though the thesis often plainly demands them.

A pronouncing glossary forms a valuable appendix, though we fear its phonetics will not be acceptable to English ears. H. G. N.

Studies in the Theory of Human Society. By Prof. F. H. Giddings. Pp. vii + 308. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1922.) 14s. net.

PROF. GIDDINGS points out that in science this century has been a time of rectification rather than of great discoveries. This applies particularly to the fundamental conceptions of sociology. These "Studies," which are always suggestive, frequently provocative, and in more than one instance illuminating, are a contribution to the revision of the theory of human society necessitated by the increased clarity and precision in scientific vision which has come about in the last twenty years. Their somewhat discursive character makes it difficult to give a concise account of the author's achievement in this direction; but, in brief, it may be said to lie in the application of a psychological interpretation to the conclusions of writers such as Darwin, Spencer, Bagehot, and Kidd, to name the more important, thereby accounting for social origins and the stages in the evolution of society in terms of the struggle for existence. Prof. Giddings's theory of human society is that social phenomena are a product of stimulus reacted to by "pluralistic" behaviour, giving rise to consciousness of kind—the "herd instinct" of other writers—from which are derived discriminating association, the ethical code, co-operation and division of labour, and, in the long run, selection and perpetuation of the adequate—the "fit" of an older terminology.

The Chemical Examination of Water, Sewage, Foods, and other Substances. By J. E. Purvis and T. R. Hodgson. (Cambridge Public Health Series.) Second and enlarged edition. Pp. viii + 346. (Cambridge: At the University Press, 1922.) 20s. net.

IN this edition the authors have expanded the chapters on water and milk, given more details on the analysis of foods and beverages, and added "an outline of elementary toxicological analysis." A very good feature is the inclusion of plenty of typical analyses. The book will be found very valuable to students preparing for the examination of the Institute of Chemistry, and can be recommended as a useful introductory treatise. Although the quoted results of water analyses are given with the acids and bases combined, there is no indication as to how the necessary calculations are to be made, and some of the sections are so condensed that it is doubtful if they are of value. A great drawback to the utility of the book is its high price.

Modern Chemical Lecture Diagrams, with Uses and Applications fully described. By Dr. G. Martin, assisted by J. M. Dickson and Maj. J. W. Christelow. Pp. 88. (London: Sampson Low, Marston and Co., Ltd., n.d.) 3s. 6d. net.

THE purpose of this book is not clear. The illustrations are found in most text-books with adequate descriptions; those supplied in the present work are often too brief to be of any service, as "Fig. 5 shows how these tubes were experimented with by Andrews and Tait." Many of the diagrams represent apparatus far from "modern." The only calorimeters illustrated are those of Favre and Silbermann; chromium is prepared by Fremy's method; sulphuric acid is concentrated in glass retorts, etc. In some cases the descriptions are faulty: Bunsen's eudiometer is ascribed to Cavendish; the Almaden process for the manufacture of mercury is called "*Distillation* of mercury," etc. As a work of three authors a more modern result might have been expected.

Forensic Medicine and Toxicology. By Dr. J. Dixon Mann. Sixth edition, revised throughout. By Dr. W. A. Brend. Pp. xi + 573. (London: C. Griffin and Co., Ltd., 1922.) 30s.

THE sixth edition of Dixon Mann's "Forensic Medicine and Toxicology," which ranks among the foremost English text-books on the subject, is the second to be edited by Dr. William Brend. It has undergone a revision which brings it completely up-to-date; a larger page is used than in previous editions, and the number of pages is reduced. The section on insanity has been rewritten on the basis of modern psychiatrical views, and that on toxicology gives additional information on poisoning by salvarsan, tetrachlorethane, T.N.T., and the gases of warfare, and on the infections formerly ascribed to ptomaine poisoning.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Relativity and Physical Reality.

IN a review by Prof H Wildon Carr entitled "The New Way of Thinking Physical Reality," which appeared in NATURE of October 7, p 471, the writer (speaking of a work by Prof Léon Brunschvicg) says regarding physical reality "According to Einstein, we cannot say, speaking absolutely, that there is any picture even for God"

It seems to follow from this that not even the Almighty himself could understand the theory of relativity If this be so I cannot help thinking that the fault lies with the theory of relativity and not with the Almighty

The writer then proceeds to say "The picture is only known as a function of the frame. That is, the things measured are only known through the measurings, and the measurings are bound up with the things they serve to measure"

This seems to imply that measurement is the fundamental thing to be considered in space-time theory, and with this I am not in agreement.

In my book, "A Theory of Time and Space," published in 1914, I showed that the ideas of measurement could be built up from the ideas of *before* and *after*, which were regarded as absolute and not dependent on any particular individual

In my smaller book, "The Absolute Relations of Time and Space," I gave an abbreviated account of this work and added an appendix showing how the various complicated geometries which are treated of in Einstein's generalised relativity could be obtained by means of a modified measure of interval

However, most relativists have been too busily engaged in praising Einstein to spare the time to go into my work

One result of this has been that, by taking the idea of measurement as the fundamental thing, a very large number, if not the majority, of relativists have fallen into the very serious error of asserting that the length of what they call a "world-line" is a minimum between any two points of it In my "Theory of Time and Space" I showed (p 360) that this is not correct

Finding that a number of writers were making this mistake, I wrote a letter which appeared in NATURE (February 5, 1920, p. 599) in which I invited attention to this matter and pointed out that in what I called "inertia lines" the length, so far from being a minimum, was actually a maximum in the mathematical sense; while, in what I called "separation lines" the length was neither a maximum nor a minimum.

In this letter I gave actual numerical examples to illustrate these points I invited attention to the matter again in my "Absolute Relations of Time and Space" (p 71), published in 1920

In spite of these efforts of mine, I again find this blunder cropping up in works published this year. Now it seems to me that it is a very important point since, in ordinary geometry, there is no such thing as a "longest" line joining two points

The idea would, I think, be apt to cause bewilderment in the mind of a person meeting it for the first time, unless it were properly presented to him. The idea of a "straight line" which was neither a maximum nor a minimum would, I fancy, cause even greater bewilderment, and he would wish to know how such lines were to be defined

In Einstein's generalised relativity, the element of interval is taken as a starting-point, although the idea of an interval in the minds of many writers is so obscure that they ascribe a minimum property to it which it does not possess

Although I have tried so often to impress on relativists that the ordinary method of treating space-time theory is unsatisfactory, I propose to make one more attempt to show that the measurement of intervals is not the simple thing that is so often supposed

Let us consider the simple time-space theory in which the length of an element ds of what I call a "separation line" is given by the formula.

$$ds^2 = dx^2 + dy^2 + dz^2 - dt^2$$

Let O be the origin of co-ordinates and let P be any point on the axis of x, at a distance l from O, measured, say, in the positive direction

Let $F(x)$ be any arbitrary differentiable function of x which is continuous and single valued, and which is equal to zero for $x = O$ and for $x = l$

Now consider the space-time curve the equations of which are.

$$y = t = F(x),$$
$$z = 0$$

It is evident that this curve passes through O and P.

But now we have

$$dy = dt,$$
$$dz = 0,$$

and so $$ds^2 = dx^2$$

Thus we have $ds = dx$, and so the length measured along the space-time curve from O to P is equal to the length from O to P measured directly along the axis of x That is, it is equal to l

Thus a space-time curve the equations of which contain an arbitrary function can have the same length between two points as the direct length measured between those points

ALFRED A. ROBB

October 11, 1922

The Miraculous Draught of Fishes—an Explanation.

WE have in the Gospel according to Saint John, in his twenty-first and last chapter, an account of the miraculous draught of fishes in the lake of Galilee for which modern research into the habits of the Galilean fishes offers a perfectly reasonable explanation. The account is as follows

"Simon Peter saith unto them [certain of the disciples], I go a fishing They say unto him, We also go with thee They went forth, and entered into a ship immediately, and that night they caught nothing But when the morning was now come, Jesus stood on the shore . Then Jesus saith unto them, Children, have ye any meat? They answered him, No And he said unto them, Cast the net on the right side of the ship, and ye shall find. They cast therefore, and now they were not able to draw it for the multitude of fishes"

Simon Peter then girded his fisherman's garment around him and leaped overboard. But the other disciples brought their boat to shore dragging the net full of fishes with them. Further on we read: "Simon Peter went up, and drew the net to land full of great fishes, an hundred and fifty and three: and for all there were so many, yet was not the net broken."

The explanation of this is to be found in a study of the habits of the fishes living in the lake of Tiberius or

Galilee. These fishes are perch-like in form and affinities, so much so that the average American angler, especially if a small boy, would call them perches. However, ichthyologists to-day place them in a family called Cichlidæ, though they were formerly called Chromidæ. By one name or another, accounts of them may be found in systematic works on fishes.

The first ichthyologist to study these fishes in their habitat was L. Lortet, who made trips to the Holy Land in 1875 and 1880, and in 1883 published an extensive memoir based on the results gained at first hand. Lortet says[1] (p. 106):

"The fishes of the lake of Tiberias, very good to eat, serve as a pasturage for the myriads of crested grebes (*Podiceps cristatus*) and of pelicans. Frequently the grebes snatch at the eyes of the chromids, and with one stroke of their long sharp beaks lift out as cleverly as would a skilful surgeon the two eyeballs and the intro-orbital partition. These unhappy fish, now blind, of which we have taken numerous examples, have thus the entire face perforated by a bloody canal which cicatrises rapidly. It is only the larger individuals who are thus operated on by the grebes, for, not being able to avail themselves of the entire fish, these voracious birds take the precaution to snatch only the morsel of their choice."

The explanation of this we find on his next page, where we are told that these chromid fishes habitually swim at or near the surface of the water.

Canon H. B. Tristram made collections of fishes in the sea of Galilee in 1864, thus antedating Lortet by eleven years, but his book, "The Survey of Western Palestine. The Fauna and Flora of Palestine," was not published until 1884 by the Palestine Exploration Fund.[2] On page 164 he refers to the Chromidæ as found in the lake of Galilee in "amazing multitudes" and continues:

"All these Chromidæ are frequently found with their eyes extracted, and their foreheads pierced by the Grebes, which prey on them, but they seem to thrive perfectly well in spite of this mutilation, and to flourish in a state of absolute blindness."

Of *Chromis tiberiadis*, the most abundant form, Canon Tristram[3] writes:

"I have seen them in shoals of over an acre in extent, so closely packed that it seemed impossible for them to move, and with their dorsal fins above the water, giving at a distance the appearance of a tremendous shower pattering on one spot of the surface of the glassy lake. They are taken both in boats and from the shore by nets run deftly round, and enclosing what one may call a solid mass at one swoop, and very often the net breaks."

Dr. E. W. G. Masterman,[4] in chapter 2, "The Inland Fisheries of Galilee," of his book, "Studies in Galilee" (Chicago, 1909), thus describes the ordinary activities of the fishermen of the lake of Tiberias:

"... their movements being directed by a man stationed on a point of the shore high above the water, who from his vantage ground is able to detect the presence of a shoal of *musht* (Chromids)." The fishermen, proceeding to the point indicated by the look-out, quickly run a net around the school. However, he tells us that the bottom everywhere is obstructed with large stones, and that the fishermen have continually to dive to free the net. This is possibly if not probably the explanation of Peter's leaping overboard.

From the excerpts given, it is plain as to the purport of the proffered explanation, if in the East, where customs change but slowly, we may interpret the past in terms of the present. Fish which go in schools at the surface of the water; fishermen who have not yet struck a school; Jesus on high ground looks over the lake, sees a school and points it out to the fishermen; they cast their nets in the direction indicated and draw them in full to the breaking point.

[2] The Palestine Exploration Fund is interdenominational in its organisation and sources of income. It has H.M. King George V. for its patron, and is supported by voluntary subscriptions. Its purpose is the thorough study of the archæology, geology, geography, history, natural history, etc., of Palestine.

[3] Dr. H. B. Tristram, Canon of Durham Cathedral, because of ill-health (lung trouble) lived in Algeria during the winters of 1855–1857. He went to Palestine in 1860 and remained for some years studying the fauna and flora, the resulting data being incorporated in his 455-page quarto volume, the standard work on the natural history of the Holy Land. In 1879 he was nominated for but declined the Anglican Bishopric of Jerusalem. He was the author of seven books on Palestine.

[4] Dr. E. W. G. Masterman is, and has been for a number of years, honorary general secretary of the Palestine Exploration Fund in Palestine.

Arabic Chemistry.

I. MAY I be allowed to direct the attention of those interested in the history of chemistry to an important paper by Prof. Eilhard Wiedemann of Erlangen? It is entitled "Zur Alchemie bei den Arabern" and is published in Heft V. of the "Abhandlungen zur Geschichte der Naturwissenschaften und der Medizin," Erlangen, 1922. It contains a translation of the passage concerning alchemy in the "Kashfu'l-Zunūn" of Hajji Khalifa, with many biographical details of the chemists mentioned. Several of these details have been provided by Prof. Brockelmann, the author of the monumental "Geschichte der arabischen Litteratur," and are entirely new. There is also a list of the most important works (with a few extracts) of the famous Aidamir al-Jildakī († 1361).

It is perhaps ungenerous to offer any criticism of so useful a contribution to chemical history, but I feel that Prof. Wiedemann's explanation of *'ilm al-mīzān* (science of the balance) as *Beziehung und Abwagung des richtigen Masses* should not be allowed to go unchallenged. As I have pointed out in the current number of *Science Progress* (October 1922), the term "Science of the Balance" as applied to alchemy refers to the proper adjustment of the *qualities* of a substance, that is, its hotness and dryness, etc., and is not used in a quantitative sense, even by Al-Jildakī, and certainly not by Jābir ibn Ḥayyān, who, I believe, originated it.

A work by Al-Jildakī which seems to have escaped the notice of Prof. Wiedemann is "Zahru'l-Kunūm," a commentary on an alchemical poem ("Qasīdatu'l-Nūniyya") of Abu'l-Aṣba 'Abdu'l-Azīz ibn Tammām al-Irāqī (wrongly named Abu Casba by Berthelot, "La Chimie au Moyen Âge," tome iii. p. 4). Ibn Tammām al-'Irāqī was a contemporary of Al-Jildakī, who thought very highly of him.

II. Berthelot (*op. cit.* p. 5) says, "Plusieurs des auteurs alchimiques arabes ont été traduits en latin, aux XII^e^ et XIII^e^ siècles, et ces traductions existent en manuscrit dans les grandes bibliothèques d'Europe. Un certain nombre d'entre elles ont même été imprimées ... dans les collections intitulées *Theatrum chemicum, Bibliotheca chemica* (*etc.*) ... A côté d'œuvres authentiques, je veux dire réellement traduites ou imitées de l'arabe, telles que la *Turba*, les écrits attribués à Rosinus, Morienus, Avicenne, etc., il en existe d'autres, fabriqués de toutes pièces en Occident, comme les prétendues œuvres des faussaires latins qui ont pris le nom de Géber."

The first part of Berthelot's statement is undoubtedly correct, although Berthelot himself was not able to discover the Arabic texts of any of the works he mentions as of probable Arabic origin

Perhaps, therefore, the following facts will be of interest.

(*a*) In a work entitled "Knowledge Acquired concerning the Production of Gold," an edition of the text of which, with a translation, I have in the press (Geuthner, Paris), the author, Abu'l-Qāsim Muḥammad ibn Aḥmad al-'Irāqī, quotes several passages which he attributes to Marianus (Morienus, *supra*), the teacher of Khālid ibn Yazīd. Many of these passages occur in the Latin "Liber de Compositione Alchemiae," ascribed to Morienus, which is to be found on pp. 509-519 of vol. i. of Mangeta's "Bibliotheca Chemica Curiosa" (1702).

(*b*) On p. 217 of vol. ii. of the latter treatise is a work entitled "Epistola Solis ad Lunam crescentem," which begins, "In tenuitate enim mina dabo tibi de pulchritudine mea lumen." This work is strongly Arabic in atmosphere, and is apparently a translation of the "Risālatu'l-shams ila al-hilāl" (Letter of the Sun to the New Moon) written by Abu 'Abdullah Muḥammad ibn Umail at-Tamīmī, who lived in the second half of the third century after the Flight (*ca.* A.D. 900). There is a manuscript of this work, with a commentary by Al-Jildakī, in the British Museum (*Add.* 23,418, xvi.). The Latin line quoted above is an exact translation of the first line of the Arabic poem; I have not yet seen the MS., so that I cannot say whether the agreement between the "Epistola" and the "Risāla" holds throughout.

The second part of Berthelot's statement, namely, that in which he expresses his opinion that Geber's works are forgeries, opens a question too wide for discussion here. I would point out, however, that Berthelot examined less than a dozen of the Arabic works of Jābir ibn Ḥaiyān, and as the latter is said to have written more than 500 books Berthelot was perhaps a little premature. Jābir, in his "Book of Properties" (a manuscript of which is preserved in the British Museum), refers to another book of his called "The Summary," which may possibly be the "Summa" of Geber. There is, moreover, in Mangeta (vol. i. p. 562) a work entitled "Testamentum Geberi"; now a commentator of Jābir's "Book of Mercy" refers to the same author's "Kitāb waṣiyya mautihi," or "The Book of his Last Will and Testament."

Evidence of this and other sorts is gradually accumulating, and it would not surprise me to find that Geber and Abū Mūsā Jābir ibn Ḥaiyān were, as for so many centuries they were held to be, one and the same.

On the Occurrence of the Archiannelids, Saccocirrus and Protodrilus, on the South and West Coasts of England.

In Nature (vol. 91, pp. 85 and 348) the present writer recorded in 1913 the occurrence—for the first time in England—of abundance of Protodrilus in many situations, and a few Saccocirrus in one situation near Plymouth, and it was shown that both these forms have the curious preference for situations near high-water mark where fresh water trickles through or over the foreshore at low water, but covered by sea water at high tide (*l.c.* 348). Since 1913 the writer has searched for and found Protodrilus in similar situations and in a large number of places between Salcombe and Falmouth, and this year was successful in taking the same animal at two places on the west coast of England, namely, on September 7, near high-water mark where the Wanson (so-called) river runs into the sea at the south end of Widemouth Bay near Bude (See Ord. Survey Map, 1 in. to mile, river Torridge, Sheet 127, 1H, 47-53), and on September 22 in a similar situation on a beach—formerly well known for shells—at Woolacombe (see O.S. Map, 1 in. to mile, Barnstaple, Sheet 119, 4C, 16-02).

In 1917 and on various occasions since, the writer has also taken large numbers of Saccocirrus (*e.g.*, 80 from a hole in the gravel about 1 ft. by 1 ft. deep in half an hour) on a beach at Portwinkle in Whitsand Bay (see Ord. Sur. Map, 1 in. to mile, Plymouth, Sheet 148, 5F, 83-15) in a position exactly similar to that described formerly (*l.c.* p. 348). This year a few individuals were also taken in the gravel on the above-mentioned shell-beach at Woolacombe. Protodrilus and Saccocirrus therefore probably occur in all suitable situations in the south-west of England, and may no doubt be recorded—after search in suitable places—from a much more extended area in the British Isles. The specimens of each genus from all localities belong respectively to one species, so far as can be gathered from external characters, namely *Protodrilus flavocapitatus*, and an apparently new and as yet undescribed species of Saccocirrus. It is hoped that the characteristic restless side-to-side movement of the head and anterior region of Saccocirrus may shortly be portrayed by cinematograph.

Living in about the same situation as Protodrilus and Saccocirrus is almost always found the planarian *Gunda ulvae*. This planarian is large and easily found under stones in pools, and therefore serves as a guide in the search for the archiannelids. The apparent positive geotropism of Gunda, which is probably true, is an interesting phenomenon and not well known; if a number of the planarians be taken on a flat stone, they can be made to change direction a large number of times by holding the stone vertically towards the light and turning it repeatedly through an angle of 180°.

The occurrence of the above-mentioned animals only in the peculiar habitat where the water undergoes violent fluctuations in salinity suggests the presence of an undetected special food supply.

Origin of the Name of the Genus Masaris.

In Ed. André, "Species des Hyménoptères d'Europe et d'Algérie," vol. ii. p. 829, it is stated that the derivation of the name "Masaris" is unknown. The first species described under this genus is *M. vespiformis* F., from Egypt; it also occurs in Algeria.

May I suggest that the origin of the name is the Arabic name for Egypt, "Masr" (also used colloquially for its capital, Cairo). As a common noun "masr" means "a fortified place," and its plural is "amsar"; the word is connected with the Hebrew word rendered "Mizraim" in Genesis. It has long seemed to me that this derivation is at least probable, and I should be glad to know if any other has been suggested.

E. W. Adair.

Turf Club, Cairo, September 26.

Fabricius, 1793, "Ent. Syst." ii. p. 283, in founding the genus Masaris, did not indicate any derivation for the name, and L. Agassiz, 1845, "Nomencl. Zool. (Hymenoptera)," masks his inability to give a derivation by the suggestion that Masaris is a proper name.

F. A. B.

American Research on Acoustics.

By Alan E. Munby.

THE Wallace Sabine laboratory of acoustics, a photograph of which is here reproduced (Fig. 1) is situated at Geneva, Illinois. It is a three-story building of brick and concrete specially erected for its purpose and forms a unique design, consisting of two structures under one roof, an inner room or sound chamber completely insulated from an outer shell. Figs. 2 and 3 show a plan and section of the building, the main feature of which is the sound chamber 27 ft. by 19 ft. and 19 ft. 10 ins. high. Here the original intensity of the sound is measured. The walls of this chamber are of 18-inch brick coated with cement outside and with wood fibre plaster inside, and the room as shown in the section has a separate concrete foundation. From this room half-way up

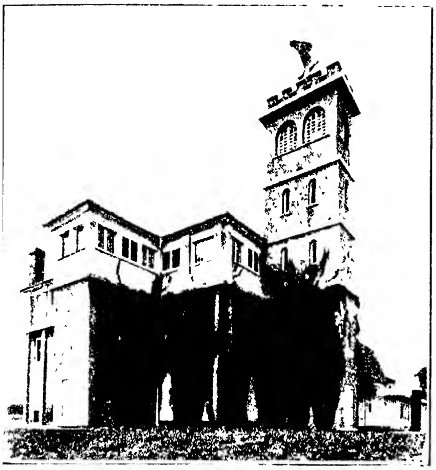

FIG. 1.—Riverbank laboratories, Geneva, Illinois.

its walls three small testing chambers are provided furnished with heavy steel doors to exclude sound completely. Materials to be tested are placed across these chambers, when the doors are opened to admit sound from an organ in the sound chamber. The organ is a complete 73 pipe instrument giving all the tones of the musical scale from C 64 to C 4096. It is operated electrically by the observer, who notes the time before a sound becomes inaudible in the test chamber. To ensure equality of sound distribution in the sound chamber a large steel reflector mounted on a central shaft is made to revolve in the room on a vertical axis. The main work, up to the late Prof. Sabine's death, has been connected with the calibration of the sound chamber and its instruments. This laborious undertaking completed, the activities of the laboratory should rapidly command a wider interest.

The present director of the laboratory, Prof. Paul E. Sabine, has recently published the results of an investigation on the nature and reduction of noises as occurring in business offices. Scarcely anything has been done in the way of investigation on the subject of noise, though the topic is obviously of wide interest. Prof. Sabine begins by pointing out that the sound-absorbing qualities of any material vary widely with pitch, and instead of attempting to apply data obtained for musical sounds, he wisely deals with the matter *de novo*, taking the actual sources of sound, such as the click of a typewriter, as the source for experimental purposes. A distinction is drawn between sounds in the open air and those in which reflection takes place, as in a room, from the point of view of the effect of the noise of one operator upon another. All but two or three per cent. of sound waves falling on a hard plaster wall are reflected, and in an experiment cited there were found to be 500 reflections before a given sound reached final decay. It would seem, therefore, that as much absorption as possible by walls and ceilings should be aimed at to prevent these reflections.

An important point brought out by these investigations is that the absorption efficiency of a given material for both musical sound and noise is greater when the material is employed in small units. In discussing practical measures Prof. Sabine alludes to linings of felt for walls, covered with some fabric, to light porous tiles and plaster, citing a plaster recently developed which is a much better absorber than ordinary plaster. He even makes a distinction between painted and unpainted walls, the general tendency of paints being to fill up a porous surface and thus decrease sound absorption, and numerical data are given showing the relative value of various surfaces in absorbing the sound of a typewriter. In these experiments the difference of power of absorption of a given material for various sounds, though existing, was found to be small.

Prof. Sabine has made a separate and special investigation of the absorption of sound by rigid walls and finds that the refraction effect on the passage of the sound into the new medium is of only trifling importance. His experiments have recently been further extended to tests upon artificial aids to hearing. He classifies the types of instruments commonly used and describes investigations to measure the difference of times during which residual sound may be heard with and without a particular instrument as a measure of the increase in loudness produced by that instrument. His results are illustrated graphically. It was observed that the highest tones in every case were less loud with instruments than without, suggesting that the short wave lengths enter the small cavity of the external ear better than do the air columns of instruments. With certain instruments also the lowest tone (frequency 128) was less well heard than without their aid. Prof. Sabine does not consider the prospects of improvements in alleviating extreme deafness to be good, but points the way by reference to the amplification of telephone currents by the thermionic tube, and he suggests a joint attack on the problem by physicists and physiologists.

Another series of experiments on sound-proof parti-

tions has recently been conducted by Mr. F. R. Watson, also of Illinois University, which are described in Bulletin No. 127 of the University. The results

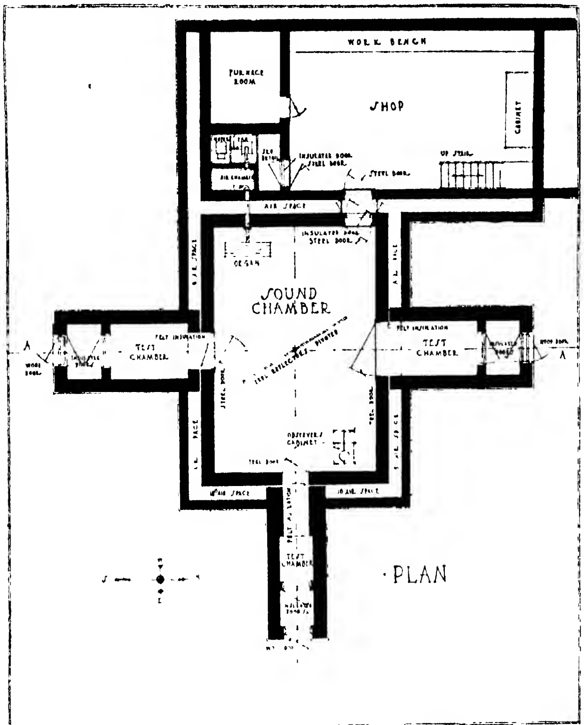

FIG. 2.—Plan of Acoustic Research Building.

have led to conclusions somewhat at variance with generally accepted ideas.

Sound, on striking an object, is reflected, absorbed, or transmitted, and usually all three results occur. In any particular case a definite amount of energy has to be got rid of in these ways, and for sound-proofing one may aim chiefly at reflection or absorption. When sound waves in one medium encounter another medium having a different density, the progression of the waves is disturbed, a certain amount of reflection takes place, some of the energy is absorbed, that is, converted into heat, while the amount transmitted through the medium will depend on its thickness and properties, such as porosity and rigidity.

In practice the materials used to separate rooms or buildings are usually of a complex character, and their rigidity will depend not only on their nature and thickness, but on the area of the separating wall. Hence the problem of assessing sound transmission is a very complex one. The author of the bulletin cited directs attention to the very detrimental effect as regards sound insulation of even small apertures caused by ill-fitting doors or by ventilators; he also makes a distinction between sounds due to air waves striking a separating medium and vibrations such as those caused by machinery, the former best resisted by heavy and rigid walling, the latter by arranging for absorption of the vibrations by beds of sand or like loose material.

From a useful résumé of previous experiments on sound transmission, the conclusion is drawn that rigidity is a deciding factor in sound prevention, and some experiments recently conducted by Prof. P. E. Sabine are cited which showed that a plate of glass three-sixteenths of an inch thick transmitted less sound than two glass plates with a sheet of celluloid sealed between them of the same total thickness. A series of tests made at the Music Building, Chicago, in 1895, is quoted, which tends to show that an air space between materials forming the two sides of a partition is of much less value for sound prevention than is commonly supposed, and that benefits which accrue from such space are almost wholly negatived by the inevitable connexion at intervals for structural reasons between the two sides.

In Mr. Watson's experiments use was made of the Rayleigh disc resonator, which admits of much more accurate and comparable results than are possible by aural comparisons adopted by many earlier experimenters. A very large number of materials were tested, and these were in all cases of satisfactory area—

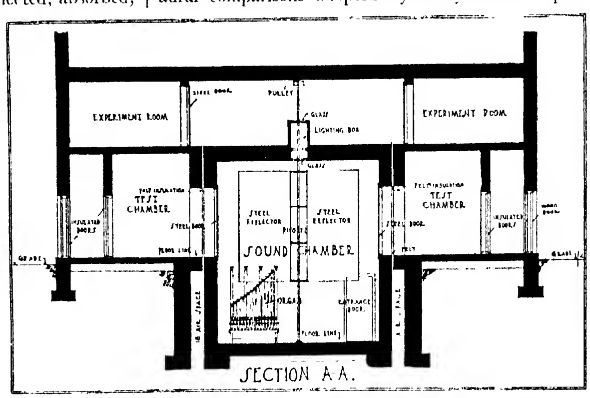

FIG. 3.—Section of Acoustic Research Building.

at least 3 ft. by 5 ft. An adjustable organ pipe blown at constant pressure formed the source of sound placed at the focus of a 5 ft. parabolic reflector facing the partition to be tested in the manner shown in

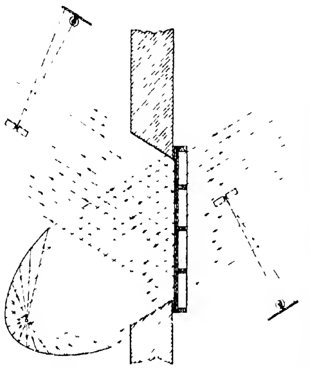

Fig. 4.—Diagram of apparatus for testing transmission and reflection of sound.

Fig. 4, and a disc resonator was placed on either side of the partition to measure the transmitted and reflected sound. Fig. 5 shows a photograph of the apparatus in use, and the observer's box provided to prevent disturbance due to his presence.

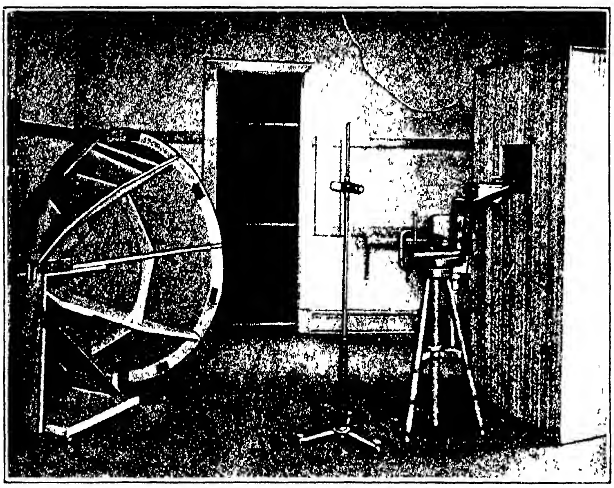

Fig. 5.—General view of apparatus.

The general results of the tests confirm the views of earlier experimenters cited. Porosity results in absorption but a good deal of transmission, while rigidity results in large reflection; the reflection from hair felt, for example, being 6, while that from Sackett board of the same thickness is 42·7.

The effect of openings such as doors were also tested, and it was found that if the transmission through a 2-inch metal lath and plaster partition has an intensity represented by 0·93, a 2-inch well-fitted solid wood door with three-sixteenths of an inch clearance from the floor increased this to 7·3 and with half an inch clearance to 11·7, showing the importance of even very small apertures. As regards composite partitions, the author's conclusions are that the small gain in internal reflection at surfaces of different density is usually more than counterbalanced by the loss in total rigidity, and thus in reflecting power of the initial surface of contact. In practice, of course, too much reflection may be detrimental to the uses of the room in which the sound is generated, and as is pointed out, absorption must be the ultimate aim for the destruction of sound, which means its conversion into heat.

Sound-proofing is of special interest in the modern type of business building, where, in order to economise space and admit of adaptability for changes of tenancy, the constructural brick wall has been so largely replaced by the thin partition, and experiments of the type described should be of great value to architects who are responsible for specifying materials and construction. The present writer's experience is that a wall composed of Fletton bricks, which are very dense, is less effective in stopping sound than one composed of stock bricks, which are more porous and less regular.

It would be unwise to generalise too much from the experiments described; with floors, for example, the direct contact produces conditions different from those of a sound wave in air, and through a solid concrete floor every footfall may well be heard in the room below. Much further work on this subject is needed, and it is to be hoped that investigation in this country will supplement and extend what is being done elsewhere.

The Galactic System.[1]

By Dr HARLOW SHAPLEY.

IN the first part of this article the main characteristics of the globular and open clusters were discussed, and it was shown how the determination of their distances led to the proposal of extremely great dimensions for the galactic system. A theory of the origin and structure of the Galaxy also seems to be indicated by the observations.

OBJECTIONS TO PROPOSED SCALE OF THE GALAXY.

Although the new values of galactic dimensions have been widely accepted by astronomers, at least qualitatively, they have been openly challenged by some. Without questioning my values (which may indeed have been unknown to him), Prof. Charlier published a few years ago provisional cluster distances that are of a wholly different order of magnitude from those I derive.[8] He had, in effect, affiliated the globular clusters with the local system of B stars. I believe he has now accepted the larger values of the distances.[9]

An extensive critical examination of my methods and results has been made by Prof. Curtis. His discussion and my reply have been published together in Bulletin No. 11 of the National Research Council

Dr Schouten has attempted to derive the distances of clusters by assuming that the frequency of absolute magnitude (the luminosity-curve) is the same in globular clusters and in the neighbourhood of the sun.[10] The method is questionable for several reasons: (1) All spectral types are lumped together by Schouten regardless of our present knowledge of the peculiar relation of type and luminosity in the globular clusters. (2) The giant-dwarf phenomenon is essentially ignored in the method (3) The observed luminosity-curves in globular clusters do not conform with the law assumed[11] (4) It is certainly improbable that the stage of evolution in any given cluster is closely comparable with the average of the many stages represented by the heterogeneous mixture around the sun (5) As applied, the luminosity-curve method involves dangerous extrapolation, for we know the frequency of magnitudes for only the very brightest stars in clusters[12]

Using the necessarily fragmentary luminosity-curves for a few clusters, Schouten finds distances averaging about one-eighth the values I have computed.

Recently, Kapteyn and van Rhijn published a valuable paper on the proper motions of Cepheid variable stars of the short-period sub-type.[13] It is generally accepted that Cepheid variables of long period are giant stars; and from the simultaneous occurrence of the long-period and short-period Cepheids in globular clusters,[14] I have assumed of course that the short-period Cepheids, which occur most frequently in clusters and serve in one of the methods of estimating the distances, are also giant stars. Kapteyn and van Rhijn, on the other hand, have computed, from the large values of the proper motion, small distances for the cluster-type variables, and therefore low luminosities. They conclude that Cepheid variables of this sub-type may be dwarfs, both near the sun and in clusters; and, by assuming that the long-period Cepheid variables in clusters are abnormalities and the short-period Cepheids are normal, they assert that the clusters may be at less than one-seventh the distances I place them. But Kapteyn and van Rhijn appear to have overlooked the decisive factor that the known radial velocities of these short-period Cepheids are remarkably high[15] (much too high, apparently, for the application of the method they use;[16] and therefore that the large proper motions they deduce and the wide distribution in galactic latitude are almost certainly the result of exceptionally high velocities in space, rather than an indication of nearness and low luminosity. Similarly, the long-period variables of spectral type M are giants at maximum, are widely distributed in galactic latitude, and have high space velocities.

As Dr. Crommelin has hinted recently in the *Observatory*,[17] a sufficient answer to those who would reduce the distance of clusters to one-fifth or one-tenth the values proposed, is that apparently they do not consider fully the dire consequences of such reduction on a vast body of other astronomical data that is now generally accepted. If the distances I give are not greatly reduced or increased these troubles do not arise; all that we know of the colours, spectra, magnitudes, and motions in the clusters, and of the clusters, then fits in well with our general stock of astronomical fact and theory.

Before we knew much about the character of stars in clusters we were not restricted by observation or theory from placing the clusters at whatever distances we liked. But now, if we alter the present distances by the amount Curtis, Schouten, and Kapteyn and van Rhijn suggest, we immediately set up peculiarities and discordances in great numbers For example, among other difficulties evoked by such changes, we would seriously question the general applicability of the spectroscopic method of determining luminosities and distances;[18] we would introduce confusion into Russell's and Eddington's theories which now so happily conform with physical laws and observational results, in clusters as well as outside; we would overthrow the period-luminosity law of Cepheid variation. Sooner or later it may be necessary to divide or multiply by 1·5 (Dr. Crommelin suggests 2) the distances I have computed for the clusters; any larger factor will entail alterations elsewhere that now appear improbably large.

It seems to me that a better line of attack on the proposed scale of the Galaxy would be to question the apparent magnitudes rather than the absolute luminosities. The latter, as we have seen, are supported by too much evidence of a varied nature to yield easily. Moreover the values of the absolute luminosities for the stars in clusters come within the range of our usual experience, whereas the apparent magnitudes (and distances) of cluster stars are quite different from those of stars we ordinarily treat.

[1] Continued from p. 547.

Since the computed distances depend equally on absolute and apparent magnitudes, they could be considerably changed, if the apparent magnitudes are widely wrong, without disturbing present ideas about stellar luminosity. The fundamental work on magnitude standards at Mount Wilson, Harvard, Greenwich, and elsewhere supply, however, a basis of unquestioned value for the cluster work. The apparent magnitudes I have observed in clusters cannot, I believe, be far wrong;[19] but has the light of these distant stars been reduced in transit so that the apparent magnitudes as observed are not a true index of distance? This question should be kept in mind, but the following points seem to show that the observed apparent magnitudes do not differ seriously from true apparent values because of a hypothecated diminution of light during its passage through space:

(1) The absence of measurable differential light scattering in space, which would appear as a dependence of star-colour on distance.

(2) The apparent restriction of known obstructing matter to regions near the planes of the local cloud and the Galaxy;[20] the globular clusters we study are practically all outside these regions.

(3) The diameter-magnitude correlation for globular clusters, which shows, almost without exception, that the globular clusters with large angular diameters are bright, and that the faint globular clusters are of small angular diameter.[21]

(4) The absence of observable proper motion for clusters, notwithstanding large space velocities.

Incidental Results

In the course of the investigation on the scale of the galactic system a number of incidental contributions of general scientific interest have been made.

I. The great distances of globular clusters provide a much more sensitive test of the degree of selective scattering of light in space than was formerly available from the studies of the colour of nearby stars. Results from many clusters, including the most remote, agree in showing no certainly measurable effect of distance on colour. We conclude that much less than one per cent. of the starlight is scattered while travelling for one thousand years through space.[22] This result, which does not hold of course for some restricted nebulous regions, indicates the extreme vacuity of interstellar space.

II. This absence of a measurable effect of distance on colour contributes an additional fact of some interest with regard to the nature of light. It is direct observational evidence that the amplitude of the light pulses of different wave lengths has suffered no differential alteration while travelling for more than 100,000 years. The age of this incoming stellar radiation, compared with that of the radiation used in laboratory experiments, is uncommonly impressive.

III. In a more definitely quantitative manner we can again use the base line in space and in time afforded by the globular clusters to derive another property of radiation. The times of maxima of several short-period Cepheid variable stars in the globular cluster Messier 5 (distance 12,000 parsecs) have been measured concurrently with blue and yellow light. Within the errors of observation no difference for the two colours is found in the time of these stellar outbursts.[23] That is, in travelling for 40,000 years, radiation that differs in wave length by 20 per cent. differs in time of arrival at the earth by less than two minutes, if at all. This is equivalent to a difference of less than one millimetre in a distance of 5000 miles. Stated otherwise, blue and yellow light travel with the same velocity with an uncertainty of less than one part in ten thousand million.

IV. In still another way can we make valuable use of the long base line provided by the remote clusters. A considerable analysis of the distribution of spectral types among the giant stars shows no measurable difference for near and distant globular clusters. This strongly suggests of course that the nearest systems are not appreciably more advanced in their evolution; but because of the finite velocity of light and the great differences in distance, they are, in our records, nearly 200,000 years older than the farthest ones. With these globular clusters we can, in effect, examine the process of stellar evolution throughout an interval of 2000 centuries. We find no evidence of change in that interval of time.[24]

Now Eddington has shown that very conspicuous advances in the evolution of a giant star would occur in less than 50,000 years, if gravitation is the main source of radiant energy.[25] We are led to believe, therefore, that gravitational contraction is not the main source of the energy that maintains the radiation of stars; it appears that the energy must come from the atom, and probably is released in the course of the transformation of the chemical elements.

The evidence for a slow stellar evolution is strongly supported, I believe, by the existence of stars, which are still in their giant stage, in the open clusters that move along the galactic plane. Dimensions now assigned the galactic system are so large that a single oscillation of a cluster must require millions of years. In fact, a greater space scale for the Galaxy practically makes necessary a long time scale and a slow stellar development. The extreme slowness with which the periods of Cepheid variables change, as Eddington has pointed out, also demands the new source of energy.[26]

V. In this connexion it may be observed that the question of the dependence of the speed of evolution on mass for a giant star is probably answered observationally by the regularly occurring phenomenon in clusters of increasing blueness with decreasing brightness. The well-known investigations by Eddington and Jeans indicate that high absolute brightness is associated with great mass, but the theory is not definite in regard to the relative rates of evolution for different masses. From the clusters we would conclude that the greater the mass the slower the development.[27]

VI. The most luminous stars in globular clusters, the spectra of which, by the way, appear to have the "*c*-characteristics" which are associated with extraordinary brightness, are more concentrated to the centre than fainter stars. This condition independently supports the inference that the most luminous are the most massive stars.

VII. The remotest object for which a definite estimate of distance has yet been made is one of these

faint globular clusters, N.G.C. 7006, for which a value of about 65 000 parsecs (more than 200,000 light-years) has been obtained, and checked by three or four different photometric methods. The most recent determination of its distance involved the discovery and study with the 100-inch reflector at Mount Wilson of Cepheid variables of the 19th apparent magnitude—the faintest periodic variable stars on record. It is likely that more remote objects, with distances as yet unmeasured, have been seen or photographed—possibly among the faintest spiral nebulæ or among the faint stars in the Milky Way.

VIII. A recent investigation of Cepheid variable stars in the Small Magellanic Cloud has shown that the very faintest variables have periods of less than one day.[28] This result, which permits the direct extension of the period-luminosity law to the short-period type of Cepheid, is further evidence of the high absolute luminosity of the kind of Cepheid variable which is most frequent in globular clusters.

IX. The proposal of a larger scale for the galactic system brings us face to face with the "island universe" theory of spiral nebulæ, which, with varying success, has for many years maintained that the spirals are other "universes" of stars—that they are galaxies comparable with our own, and that our Galaxy, seen from a sufficient distance, would appear as a spiral nebula. A theory of "comparable galaxies" immediately becomes very difficult to maintain along with the larger dimensions of the galactic system. In a paper published three years ago I discussed at some length this problem of external galaxies.[29] The conclusion reached at that time, that the nebulæ of the spiral family are probably neither galactic in size nor stellar in composition, has been strengthened rather than weakened by subsequent investigations, particularly by van Maanen's remarkable work on the motions in the brighter spirals.[30]

X. Since the brighter spiral nebulæ, according to the present view, are probably within the boundaries of our galactic system, it may be that the novæ occurring so frequently in the Andromeda nebula represent the encounter of this enormous, rapidly moving object with galactic stars. The suggestion is in harmony with the Seeliger-Monck hypothesis of the cause of ordinary novæ, and, moreover, it is in line with the only hypothesis that has yet been advanced to account for the peculiar irregular variable stars in the diffuse nebulæ, such as those in Orion.[31] This interpretation of the variables of the relatively near Orion nebula would certainly be of significance for historical geology, since disturbances of our sun, much less serious in character than those observed for novæ and for the Orion variables, would be of paramount importance in matters pertaining to terrestrial climates and organisms.[32]

XI. Conversely we can use the geological records to show that the radiating equilibrium of the sun probably has been uncommonly stable compared with that of many stars. The investigation at Harvard under Prof. Bailey's direction of the frequency of galactic novæ brought out the remarkable result that at least fifteen novæ brighter than the tenth magnitude at maximum, have appeared every year during the last three decades.[33] If a frequency of even one-fifth that amount has been maintained throughout the hundreds of millions of years of approximately constant solar radiation (shown by the geological records), more novæ have occurred than there are known stars. Our sun, however, which has certainly escaped not only disasters of this kind but even much less serious disturbances, apparently moves in an uneventful region of space.

XII. The attractive and somewhat futile speculations on the probability of the occurrence of protoplasmic life and its slow evolution elsewhere in the sidereal system must, of course, take account of the frequency of these calamitous stellar outbursts that we call novæ.

In connexion with this attempt at a partial interpretation of galactic structure it might be well to emphasise the following points.

(1) Many of the fundamental laws and assumptions of physics are involved in this sidereal superstructure, so that developments in thought or observation, which hereafter greatly affect these laws and customary assumptions, may at the same time seriously disturb existing conceptions of the sidereal system.

(2) The complete elucidation of the source of stellar energy may bring with it modifications both in our views of the evolution of stars and in our assumption of the importance of gravitational organisation of stellar bodies.

(3) The question of the obstruction of light in space is not in a satisfactory condition, and the nature of the radiation of the diffuse nebulæ is little understood; we have essentially no information concerning the pregiant stage of stars and its relation to the diffuse nebulæ, and the dust and gases in space.

(4) Cepheid variables, though comparable with each other, may possibly be sufficiently different from other stars that we cannot use their speed of evolution as a quantitative measure of the speed of evolution for all stars.

For the present I take little heed of these warnings, and merely record them as examples of underlying uncertainties. They serve to remind us that the conclusions are based not only on favourable observations and theory, but also on the absence (for the time being) of seriously unfavourable data.

12. I first tried out the method six years ago (*Mt. W. Contr.* 116, p. 81), but abandoned it as wholly unsuited to the brighter stars in globular clusters. The Kapteyn luminosity curves for separate spectral types, however, may be of high value.
13. Bul. Ast. Inst. Neth. No. 8.
14. Kapteyn and van Rhijn state that eight Cepheids of long period are known in two globular clusters. In my paper from which they get their data (*Mt. W. Contr.* 151) I show that twelve long-period Cepheids occur in the five globular clusters Messier 3, 5, 13, 15, and Omega Centauri. Four of these clusters contain also large numbers of short-period Cepheids only one or two magnitudes fainter than the long-period Cepheids. Unpublished results obtained at Harvard show that long-period Cepheids occur in other globular clusters.

Current Topics and Events.

IN an article on Lord Inchcape's task in the *Sunday Times* of October 22, a former finance member of the Government of India, Lord Meston, makes an alarming suggestion Speaking of things "useful, but not essential," he says "many of the research institutes and the like will come under the shears" The illiberal spirit which inspired our domestic wielders of the axe may thus be carried by one of them to India—a country which, more than any other, perhaps, has benefited by the application of science to "useful" purposes. The plant breeders there, alone, have literally added millions to the country's wealth, new wheats and cottons yielding 20 to 30 per cent more than the indigenous varieties have already been successfully introduced It must not be forgotten that, in India, the prosperity of agriculture is a fundamental element of the solvency of the Government, for there, the State, as owner of the soil, takes one half of the rental value of the land The sum thus raised approaches a moiety of the whole taxation of the country It is to be hoped that such a suicidal policy as that indicated by Lord Meston will not be advocated by Lord Inchcape, though as a quondam member of the Geddes Committee he may be inclined to repeat its mistakes

THE French airman, M Maneyrolle, won the prize of 1000*l* offered by the *Daily Mail*, by a wind flight on October 21 lasting three hours and twenty-two minutes. The notable successes registered during the recent French contests, and especially during the German contests, raised the question whether British ...rs could rival the feats of their foreign colleagues, and the offer of a prize of 1000*l* by the *Daily Mail* ...ed to the organisation, at Itford Hill and Firle Beacon on the South Downs, of the first British gliding contests since the war, which commenced on October 16 and continued through the week Additional prizes were offered by the Royal Aero Club and others The entry of British machines and pilots was very encouraging, there being some two score British ...ers, besides foreign aviators, notably the Dutch airman, M Fokker A large number of short flights and some quite long flights were made, yet on the whole the results of the meeting were not of a sensational nature until the last day of the meeting The general conclusion is that British aviators do not fall behind those of Germany, and that it is possible to find suitable arenas in this country for the practice and display of motorless flight The most notable achievement of the first day of the contest was a thirty-seven-minute glide by M Fokker, but this was surpassed by a fine flight executed by Mr F P. Raynham. This aviator had already taken a place in the front rank of British pilots in the recent air-race round England he added to his laurels by remaining in the air in a motorless machine for one hour and fifty-three minutes, thus putting himself in the same category as the German record-makers, Martens and Hentzen But on the last day, Saturday, two world-records were nevertheless established J R Olley went up in a Fokker biplane, and remained in the air with a passenger for forty-nine minutes, while M Maneyrolle, in a tandem monoplane glider, succeeded in remaining in the air for three hours twenty-two minutes, thus winning the *Daily Mail* prize and beating the previous record, that of Hentzen, by twelve minutes During the last ninety minutes of his flight, M. Maneyrolle was accompanied by a monoplane glider flown by Squadron Leader A Gray, and it was night when the two machines landed within 100 yards of the point from which they started These competitions on the South Downs will serve as an encouragement to motorless flight in this country, and will help in the accumulation of knowledge and experience on one of the most interesting developments in modern aeronautics

THE height of the ground at Firle Beacon, where the gliding competition referred to in the foregoing paragraph was held, is 718 feet above sea level, and it slopes downwards somewhat to Itford Hill, which is situated about three miles to the westward The gliding was chiefly from one or other of these positions The meteorological conditions during the week could not be considered altogether favourable, and there was wide difference in the weather on the several days At times the winds were too boisterous and unsteady for gliding, while at others the gliding was hampered by winds which were too light or by cloud and mist, the direction of the wind was chiefly from between north and east On the closing day, Saturday, the surface wind was blowing at the rate of about 20 to 30 miles an hour, and M Maneyrolle, in his record flight, kept mostly at about 200 feet above ground The controlling conditions of the weather were similar throughout the week, a region of high barometer was situated to the north of Scotland and a region of low barometer was fairly stationary over the north of Spain All who took part in the gliding contest, however, would know well what different weather could be experienced with similar controlling conditions.

AT a meeting of manufacturers held on October 18 at the Institution of Electrical Engineers it was unanimously agreed, in view of the approval of the Postmaster-General to the memorandum and articles of association of the British Broadcasting Company having been obtained, to proceed with the registration of the company The capital of the company,

amounting to 100,000*l*. in 1*l*. shares, has been guaranteed by the British Thomson-Houston Company, General Electric Company, Marconi's Wireless Telegraphy Company, Metropolitan-Vickers Electrical Company, Radio Communication Company, and the Western Electric Company. *Bona-fide* British manufacturers alone will be allowed to join the broadcasting company and may take up one or more shares. The guaranteeing companies are immediately responsible for 60,000*l*. of the capital, and the balance of 40,000*l*. is offered for subscription; should applications be received for a number of shares in excess of the balance mentioned, the guaranteeing companies will reduce their holdings with the view of meeting the applications of other manufacturers. Lord Gainford has consented to become the chairman of the board of the broadcasting company, which, in the words of its memorandum, is a public utility service for the broadcasting of news, information, concerts, lectures, educational matter, speeches, weather reports, and theatrical entertainments. Each member of the broadcasting company is required to make a deposit of 50*l*., returnable to him when he withdraws therefrom; he must also enter into an undertaking neither to sell any apparatus, except batteries, accumulators, and aerial equipment, not made in this country, nor to make broadcasting apparatus for any person who is not a member of the company. For transmission purposes, every member owning an invention must give the use of the same to the company, *i.e.* all patents are to be pooled, so that the broadcasting company will be free of royalties. The expenses of broadcasting are to be met partly from the fees collected on broadcasting licences, the Postmaster-General having agreed to pay over one half of the 10*s*. to be charged for each licence to the company, and partly by contributions, on a royalty basis, to be made by the members of the broadcasting company; the scale of these contributions ranges from 2*l*. 5*s*. in respect of each three-valve set to 2*d*. in respect of each single valve sold. The date for opening broadcasting services has not yet been definitely fixed.

AT a joint meeting of the Royal Geographical Society and the Alpine Club on October 16, General the Hon. G. C. Bruce, Mr. G. L. Mallory, and Mr. G. I. Finch gave accounts of the recent expedition which failed by 1700 ft. to reach the summit of Mount Everest. Mr. Mallory said that in light of the experience gained this year the problem of climbing the mountain must be reviewed afresh. The most important modification must be in respect of porters. On this expedition porters had carried a camp to 25,500 ft. and had shown astonishingly little fatigue. It seemed certain that after a night's rest at 25,000 ft. the porters could carry a camp to 27,000 ft. If this could be done, it would facilitate the task, which would then depend on the endurance of the trained climbers. This would entail a climb of 2000 ft. and the corresponding descent in a day. The effort of climbing the last 2000 ft. should not be considerably greater than that of climbing from 25,000 ft. to 27,000 ft., for the difference in atmospheric pressure is only 0.8 in. between 27,000 ft. and the summit, compared with a difference of 19.5 in. between sea-level and 27,000 ft. But the fatigue of the previous days' efforts and possibly the ill-effects of sleeping at high altitudes would tell against the climber on the last lap. Mr. Mallory is not inclined to think that with the help of oxygen the feat was impossible. A significant fact was that three climbers at a height of 27,000 ft. felt no special distress. Two other considerations must be borne in mind: the danger involved in avalanches and in the possible loss of muscular power, and the difficulties due to weather. The latter was most serious. Unless the bad weather of this year was abnormal, the weather factor reduced the likelihood of men reaching the summit of Mount Everest and descending in safety.

IT was stated in NATURE for September 16, p. 394, that a committee had been appointed to work out a proposed Federation of American Biological Societies. The constitution proposed by that committee is published in *Science* for September 29. It follows the main lines adumbrated in our previous note. We are glad to observe that, in the opinion of the committee, the Federation should in no way conflict with existing organisations but should rather strengthen their efforts and should avoid unnecessary duplication of effort and expenditure. It proposes therefore to act in close co-operation with such existing agencies as the American Association for the Advancement of Science and the National Research Council. The kind of work that may be undertaken by such a Federation appears from the fact that the proposed constitution calls for the appointment of a Committee on Bibliography and Publication to act in co-operation with similar committees that may be appointed by the two bodies just mentioned. It may be remembered that the British Association has a committee dealing with the zoological branches of this subject and that the recent Conference of Corresponding Societies requested the Council of the British Association to inquire into the general question of scientific bibliography.

MR. SPURLEY HEY, Director of Education in the city of Manchester, has been moved by our article on "Children and Museums" (NATURE, September 2, 1922) to send us a report on the lectures for elementary school children in the Museums and Art Galleries of Manchester. We were well aware of the admirable work begun in Manchester as a war measure, but found so successful that it has since been continued and extended. Classes are at present held in six institutions, and it is hoped to include three others. Of the eleven demonstrators engaged, nine are certificated teachers. Every attempt is made to co-ordinate the museum work with the inside work of the schools. There seems to be a larger demand for the science courses than for those at the art galleries, but all the courses are exceedingly popular with the children. The general opinion seems to be that these classes awaken the intellect of the children. It is natural that they should help them in such subjects as geography and science, but it appears that they also improve their drawing, teach them in

a practical way the elements of civics, cultivate their manners, and even give the children an increased pleasure in poetry. Indeed there is scarcely a side of education that is not improved in this way. We are not in the least surprised, and we commend Mr. Spurley Hey's report to all educationists as well as to those museum authorities at whom our previous remarks were aimed.

COMMANDER FRANK WILD, leader of the Shackleton-Rowett Expedition after the death of Sir Ernest Shackleton, and Mr. John Quiller Rowett, who financed the expedition, had the honour of being given an audience by the King on Monday morning. The King expressed his deep regret for the untimely death of Sir Ernest Shackleton, and complimented Commander Wild on the successful work accomplished.

WE much regret to announce the death on October 27, in his eighty-second year, of Mr. W. H. Wesley, for forty-seven years assistant secretary of the Royal Astronomical Society.

THE second annual meeting of the Deutsche Gesellschaft für Vererbungswissenschaft was held in Vienna on September 25-27. Though technically a meeting of the German society only, in fact the congress was largely international in character, the visitors including representatives from England, America, Italy, Switzerland, Japan, Holland, and the Scandinavian countries. Prof. R. Wettstein presided, and the opening address was delivered by Prof. E. Baur (Berlin). The principal discussions were opened by Prof. Goldschmidt (Berlin) on "The Mutation Problem," and by Prof. Ruedin (Munich) on "The Inheritance of Mental Defects." Among the papers which were read and briefly discussed were the following: the modification of sex factors in fungi, by H. Kniep; relative sexuality, by M. Hartmann; *experimenta crucis* on the inversion of sex, by R. Goldschmidt; experiments with hermaphrodite frogs, by E. Witschi; linkage in antirrhinum, by E. Baur; the deficiency phenomenon in Drosophila, by O. L. Mohr; methods of obtaining different sex-proportions in Drosophila, by G. Bonnier; polymery in butterflies, by H. Federley; parthenogenesis, gynandromorphism, and the determination of sex in phasmids, by H. Nachtsheim; Blakeslee's experiments on heredity in Datura, by C. B. Davenport; the influence of temperature on the offspring of rats, by H. Przibram; the influence of light on butterflies, by E. Biecher; genetic studies in barley, by E. Schiemann; vegetative segregation in *Lupinus angustifolius*, by H. Roemer; transplantation and relationship, by Fr. Erdmann; the inheritance of Hæmophilia and its importance for our conception of the nature of genes, by H. K. Bauer; and variability and the formation of species, by P. Schlesinger. Demonstrations were arranged in the zoological laboratory of the University and in the Natural History Museum. Visits were made to the Biologische Versuchsanstalt (where Prof. Steinach demonstrated his transplantation experiments in rats and guinea pigs) and to the principal libraries and art galleries in the town. Prof. R. Hertwig was elected president for the ensuing year, and the society accepted his invitation to meet at Munich in 1923.

AN international exhibition of technical, artistic, and scientific photography, optics and cinematography, with a section for the history of photography, will be held in May and June of next year at Turin, Italy. Information can be obtained from the Comitato dell' Esposizione Fotografica, presso la Camera di Commercio, Torino, Italy.

THE council of the Hancock Museum has appointed Mr. T. Russell Goddard, at present assistant curator at the Sunderland Museum, to the position of curator of the Hancock Museum, Newcastle-upon-Tyne. Mr. Goddard was trained under Mr. Montagu Browne, and then worked on the staff of the Leicester Museum under Mr. E. F. Lowe for six years, arranging and classifying the local fauna and flora. Thence he proceeded to engage in biological research work in the laboratory of Dr. C. F. U. Meek, previous to his appointment at Sunderland about two years ago.

WE have received the second quarterly issue for this year of *Process Work and the Printer*, which contains among other interesting items an article on "The History of Printing Types," reprinted from the *Printing Supplement* to the *Manchester Guardian*. It is illustrated with many specimens from Gutenberg's first type (1455) to those of the present day. One of the three inset illustrations is a photogravure in colour, but the original water-colour drawing is of such a character that it is not possible to judge of the quality of the reproduction. The editor states that it marks a notable departure in photogravure printing in that it necessitates the printing of a large edition instead of only a few proofs as has hitherto been the case in colour photogravure.

THE Cantor Lectures delivered recently before the Royal Society of Arts by Prof. Arthur M. Hind, Slade professor of fine art in the University of Oxford, on "Processes of Engraving and Etching," are printed in the Society's Journal for September 22. The lecturer does not treat the subject as a practical engraver, but from the point of view of the historian and critic. He seeks chiefly to discriminate the characteristics and limitations of the various processes, and their peculiar fitness for certain kinds of work. The subject is richly illustrated by reference to a very large number of examples. Prof. Hind concludes by stating that "perhaps the greatest danger to recent etching has been its popularity; the public has preferred a bad etching to a good woodcut or lithograph, leaving these other arts a safer though less prosperous field. It is perhaps on that account that some of the best etchers are those who have exhibited least."

DR. GEORG BERG has written to us with reference to a review of his work on ore deposits published in NATURE of August 12, p. 205, to point out that the reviewer has done him an injustice in stating that he restricts the term syngenetic deposits to magmatic segregations. In this correction Dr. Berg is undoubtedly right; he does include among syngenetic deposits such ore beds formed by sedi-

mentation as have undergone no chemical change since their deposition, as well as clastic deposits Unfortunately, he has dealt with the former type of syngenetic deposits (magmatic segregations) first, has then passed to the study of epigenetic deposits, and then, after some 280 pages out of a total of 400 devoted to epigenetic deposits, he reverts to the last two classes of syngenetic deposits, and this method of dealing with the subject caused the reviewer to overlook the fact that Dr Berg had commenced by stating that these two last classes (ore beds and clastic deposits) were also syngenetic This explanation will, we trust, suffice to remove the wrong impression created by the comment to which Dr Berg refers

MESSRS. W. HEFFER AND SONS, Ltd., are bringing out "Fundamentals of Bio-Chemistry in Relation to Human Physiology," by T. R. Parsons, which is intended to form an introduction to the study of the chemical processes at work in the body. It is addressed more particularly to medical students reading for examinations in physiology. Another forthcoming book in the same publishers' list is "The Ethnology of the American Indians," by Dr. P. Radin, in which particular stress is laid upon a clear delineation of the civilisations of Mexico and Peru and their influence on the culture of the other parts of America A useful feature of the volume should be the detailed and critical bibliography it is to contain

Our Astronomical Column.

A NEW COMET — A new comet, 1922 c, was discovered by Dr Baade at Bergedorf Observatory, Hamburg, on October 19, and observed by Prof. Stromgren at Copenhagen on October 22, 8^h 15^m G M T, in R A 19^h 52^m $57{\cdot}7^s$, N Decl $36°$ $57'$ $38''$. He gave the magnitude as 9 0, so the comet should be visible in small telescopes Assuming uniform motion, the following are the positions for the dates named at 8^h P M

	R A	N Decl
Oct 28	20^h 6^m 2^s	$35°$ $22'$
,, 31	20 12 35	34 33
Nov 3	20 19 8	33 44

The comet is in Cygnus, and is due south, 15° from the zenith, at 5^h 30^m P M

SPECTROSCOPIC PARALLAXES FOR TYPE A — The spectroscopic method has hitherto been limited to spectral types F G K M A paper by Messrs Adams and Joy (Proc Nat. Acad Sci, July 1922) gives the details of an investigation as to its extension to type A It had already been noticed that there was a difference in the general sharpness of the spectral lines in stars of this type, and on examining the stars the distance of which is known either by trigonometrical, hypothetical, or moving-cluster parallaxes, there is found to be a distinct correlation between absolute magnitude and sharpness of lines Using the letters s, n to denote sharp and nebulous spectra, they give the following values for the absolute magnitudes of different types. A1 s 0 0 n 1·2, A2 s 0 6 n 1 5, A3 s 1 2 n 1·7, A4 s 1 5 n 1 9, A5 s 1·8 n 2·1, A6 s 2·1 n 2 2 After this point the two coalesce They apply the formulæ to the Taurus group and the Praesepe, finding parallaxes of 0″ 024 and 0″·011 respectively. Certain stars had already been classified at Harvard as C-stars They have very sharp and narrow lines, and the enhanced lines, especially those of strontium at 4077 and 4215, are very intense There is reason to think that these stars, of which α Cygni is the most prominent example, are super-giants, to which the preceding formulæ do not apply They are very luminous and very remote, but material for assigning parallaxes is at present wanting The authors note that in all spectral types sharpness of lines is associated with high luminosity They explain this by the very low density of the giant stars

A paper by Mr Evershed in the Mon Not. R A S for last May noted that there were many broad hazy lines in the spectrum of Sirius; he pointed out that in Sir Norman Lockyer's classification, Sirius is on the descending side of the temperature curve, and quotes his words that in stars of this class the hydrogen lines are relatively broad Mr Evershed is inclined to explain the widening as a Doppler effect due either to rapid rotation or strong convection currents But, whatever the cause, the facts are in accord with the results of Adams and Joy

GLOBULAR CLUSTERS IN THE LARGE MAGELLANIC CLOUD — In Harv Coll Observ Bulletin, No 775, is announced the discovery that five objects formerly catalogued as nebulæ are definitely globular clusters. Their N G C numbers are 1783, 1806, 1831, 1846, 1978 The status of two others, Nos 1651, 1866, is doubtful The detection of new globular clusters is interesting, since it was announced a few years ago that probably all objects of this class within our reach had been detected. It also enables a new estimate to be made of the distance of the cloud, using Prof Shapley's formulæ At present only the simple formula based on apparent diameter has been applied The diameters of the above five objects are 1′·9, 1′ 6, 1′·9, 1′ 8, 1′ 8 The corresponding distance is 35 kiloparsecs, or 110,000 light-years This is of the same order as Hertzsprung's estimate. It makes the linear diameter of the large cloud 4½ kiloparsecs, so that it is comparable in size with our own star system, leaving the outlying galactic extensions out of account

VARIABILITY IN THE LIGHT OF IRIS — Prof Wendell noted in 1904 that this minor planet was variable in light to the extent of 0 35 mags in 0·259 days Mr. Campbell found the same period but a smaller range in 1917 But Miss Harwood at the Maria Mitchell Observatory finds no variation in the present year The case is like that of Eros, and may arise from irregular shape of the object, the amount of variation depending on the direction of the line of sight, it has been suggested that a further complication might arise from a shift in the axis of rotation in the body of the planet, if it were rotating about an axis other than a principal one The shape of the asteroids might give a clue in questions of cosmogony, hence such researches are useful In the case of Eros, when observed for parallax there is the possibility of error if the centres of light and of gravity are non-coincident. Mr. Hinks, indeed, found some evidence of a small oscillation of this kind, but the effect would probably disappear in the mean of many observations.

Research Items.

EARTHWORKS IN AMERICA.—The Peabody Museum of American Archæology and Ethnology, Harvard University (vol. viii No 3), has issued a monograph by Mr. C. C Willoughby on the Turner group of earthworks in Hamilton County, Ohio, with notes on the skeletal remains by Mr. E A Hooton The book, admirably illustrated by sketches and photographs, gives a full account of these interesting structures Mr Willoughby remarks that the builders attained a degree of excellence in art design probably unsurpassed north of Mexico It is important to note that they show no affinity with the people of the Madisonville site, beyond those which are common to all Indians Their affinities are rather with the Eastern dolichocephals, although there is present a brachycephalic element such as is often found among the Eastern Indians.

LONG BARROWS IN THE COTSWOLDS AND WELSH MARCHES.—Under the title of "Notes on the Archæological Information incorporated in the Ordnance Survey Maps," Mr O G. S. Crawford, Archæology Officer, Ordnance Survey, has published a useful pamphlet with a map showing the position of the Long Barrows and Stone Circles in the Cotswolds and the Welsh Marches He remarks that the fact that the Cotswold limestone area is a region of relatively high elevation has led some to suppose that this accounts for the abundance of long barrows in this district But the factors which influenced prehistoric man in the choice of a settlement were not elevation but vegetation and water supply Prehistoric man selected these limestone areas when the soil favoured an open growth of vegetation, because many regions of high elevation, such as the Black Mountains, are entirely devoid of long barrows He chose sites where the streams are more numerous, and in Monmouthshire the position of two out of the three long barrows shows that Neolithic man did not shun the lowlands when they served his purpose Mr. Crawford's introductory essay is interesting and suggestive, and it may be hoped that archæologists will soon be in possession of similar maps indicating the position of prehistoric remains in other districts

THE PAINTED GLASS OF GLOUCESTER CATHEDRAL.—In that gem of ecclesiastical architecture, the Lady Chapel of the Abbey, Gloucester, the east window, a work dating from the end of the 15th century, at once attracts attention But the glass is in such a confused and disordered state that the ordinary spectator is scarce able to distinguish any definite subject, and carries away the impression of a mere mass of richly toned fragments, with here and there a face or a form dimly visible The scheme of the window was obviously to illustrate miraculous stories about the Virgin, but hitherto little has been done to arrange the fragments in a definite way In the Transactions of the Bristol and Gloucestershire Archæological Society for 1921 (vol xliii) Mr G M'N Rushforth, working on a catalogue prepared in 1915 by Mr J D. Le Couteur, a well-known authority on medieval glass, publishes an exhaustive paper, supplied with good photographs Many of the figures and incidents have now been satisfactorily identified, and much new light is thrown on an important collection of 15th century painted glass

GERMINATION OF INDIAN BARLEY.—Experiments on the influence of atmospheric conditions on the germination of Indian barley have been carried out by Mr W. Youngman, Government economic botanist, United Provinces, and the results, which have been published as a memoir of the Indian Department of Agriculture, are summarised in the *Bulletin of the Imperial Institute* (vol 20, No 2) It was found that if barley is exposed to an atmosphere containing a large amount of moisture, its germinating capacity is seriously reduced and may even be destroyed entirely Such a condition of the atmosphere exists in North-eastern India during the period of the monsoon, *i.e.* after May, and consequently the germinating power of barley shipped from Calcutta after May is liable to be low Barley produced in North-western and Central India would not meet with adverse conditions at any time, and although the humidity of the atmosphere along the sea-board area from Karachi to Bombay is high after May, barley exported at that period from these ports would not suffer appreciably if it were not delayed long in the sea-board area. In 1912–13 nearly 300,000 tons of barley, of a total value of about 1¾ million pounds sterling, were shipped from the various ports, about two-thirds from Karachi, slightly less than one-third from Calcutta, and a small quantity from Bombay No barley has been exported to this country from India during the last three or four years, but when shipments are again made, the results of this work should be borne in mind

PALÆOBOTANY AND EARTH-HISTORY.—The importance of the correct determination of fossil plants from the point of view of stratigraphers is well brought out in two short papers by Prof A C Seward in the Quarterly Journal of the Geological Society of London, vol 78, part 3, Sept 1922 In one, the first fossil plants recorded from Ceylon are described, from specimens collected in dense jungle by Mr E J Wayland They prove the existence of Middle Jurassic strata, comparable with those of Madras The second paper deals with Carboniferous plants collected by Mr J A Douglas on the west coast of Peru Dr F Fuchs recorded plants from this locality as Carboniferous in 1900, but he included two Wealden species, which Prof Seward is inclined to reject in the absence of further evidence If the list now given could be regarded as representing a flora of Upper Carboniferous age, its north-European affinities and the absence of any member of the Glossopteris flora would give it special significance Prof Seward, however, states that it may be Lower Carboniferous Mr J A Douglas, in the discussion on the paper, suggested that a chain comparable in height with that of the existing Andes may have formed an effectual snow-clad barrier between the region supporting the Gondwanaland flora and that yielding a more normal Carboniferous type farther to the west

AMERICAN VERTEBRATE PALÆONTOLOGY.—A number of short "Contributions from the Paleontological Laboratory" of the Peabody Museum, Yale University, have of late been appearing in the *American Journal of Science* (vols ii to iv) E L. Troxell, from "A Study of Diceratherium and the Diceratheres," is led to divide the true Diceratherium, Marsh, of the Great Basin of Oregon, from those of the Great Plains of Nebraska and Wyoming, which he refers to a new genus Menoceras, and further to separate both from Aceratherium, Kaup The same author, treating of "Oligocene Rodents of the genus Ischyromys," hazards the suggestion that this genus developed into the modern prairie-dog, Cynomys. Mr Troxell has also investigated "the genus Hyrachyus," which he considers divisible into three groups R S Lull supplies a "Restoration of *Blastomeryx marshi*" and discourses on the "Primitive Pecora in the Yale Museum," among which with other novelties is described *Nanotragulus loomisi*, gen.

et sp nov, from the Miocene of Wyoming. M R. Thorpe describes a "New genus of Oligocene Hyænodontidæ," from South Dakota, under the name of Neohyænodon He also discusses the "Oregon Tertiary Canidæ" and "A new Merycodon" as well as "Aræocyon, a probable old world migrant" The last-named, founded on a jaw from the Middle Pliocene of Oregon, has its nearest ally in *Simocyon primigenius*, Roth, from the Pikermi beds near Athens, and should it prove to be a derivative of purely American ancestry it will, the author considers, be one of the most remarkable cases of convergence known to the science of vertebrate palæontology Finally, in a more lengthy paper Mr Thorpe describes "Some Tertiary Carnivora in the Marsh Collection," including new forms

RAIN-PRODUCING INFLUENCES IN SOUTH AUSTRALIA — From an examination of the rainfall records and other evidence in South Australia, Mr E T Quayle has come to the conclusion that there is an area of marked rainfall improvement lying south-east from Lake Torrens, where in places it ranges as high as 20 per cent In the Proceedings of the Royal Society of Victoria, 34 (N S), Pt II, Mr Quayle discusses the reasons of this improvement and its bearing on the reclamation of arid areas in the interior The area of improvement in South Australia is continuous with a similar one in Victoria, and both are in contrast to areas of marked decrease to the north Irrigation as a source of improved rainfall cannot operate in South Australia, for it has made practically no progress Mr Quayle finds the causes in changes in vegetation, due to settlement, and to variations in the water supply of the great inland lakes From various data it would appear that Lake Torrens and Lake Frome are now impounding more water than formerly, but quantitative data are difficult to obtain Certain places to the south-east or lee of the lake show increased rainfall in recent years, while places beyond its influence show a decrease The full cause of the increase of water in these lakes is not clear, but Mr Quayle considers that the substitution of cereal crops or grass for Mallee scrub leads to a marked increase in rainfall The destruction of forest trees and the extension of pastoral lands are aids in local rain production This matter is of so much importance that it is to be hoped that investigations on a larger scale will be undertaken

THE LIGNITE OF THE LOUGH NEAGH CLAYS — Evidence is accumulating to show that the Lough Neagh Clays in the counties of Tyrone and Antrim are of Oligocene rather than Pliocene age The recent deep boring at Washing Bay has yielded to Prof Johnson and Miss J G Gilmore (Sci Proc R Dublin Soc, vol 17, p 59, 1922), through the cores preserved by the Geological Survey, material that calls forth the following interesting remark "It needs little imagination to picture the presence of forests of Sequoia in N Ireland, possibly contemporaneous with those in S Devon at Bovey Tracey, the shores of the Baltic, the Rhine valley, Saxony, Silesia, and S France We may yet find in Ireland large deposits of lignite or brown coal of economic value like those abroad"

THE STATEMENT OF CRYSTAL-SYMMETRY — Numerous minerals are known, the normal crystals of which indicate, on physical measurement, a certain type of symmetry, while the results of treating them with solvents lead to their being placed in another of the thirty-two crystallographic classes A latent symmetry is thus revealed E T Wherry (*Amer Journ Sci*, vol 204, p 237, Sept. 1922) styles such crystals *amphisymmetric*, and regards the symmetry determined with the goniometer as that of the structure built up by the atoms or molecules, and the latent symmetry as that of the separate atoms or molecules, with their attached electrons This matter is ingeniously stated on p 241 A halogen atom in sylvine, for example, may receive an electron from a potassium atom, and may then, as a complete octet, be capable of taking its place in a holosymmetric structure When, however, it is attacked by a solvent, its low surface-symmetry, due to the presence of one electron of metal and seven of halogen, is revealed as the latent symmetry of the substance Both classes of symmetry should be mentioned in the description of the crystal Sylvine might thus be described as "Cubic, structurally holosymmetric, latently gyroidal," or "Cubic, structurally of class 32, latently 29" A useful list of amphisymmetric substances is given by the author, including some not known as minerals

INSULATION TESTING — Messrs Evershed and Vignoles, Ltd, of Acton Lane Works, Chiswick, have produced a new insulation tester which possesses several advantages over the older types Mr Evershed, who was the first to make a testing set consisting of a small hand dynamo and an ohmmeter, has produced many improvements on the original set during the last thirty years His greatest improvement was when he made a "one-box" instrument in 1903 and raised the pressures produced by the hand dynamo to 500, 1000, and even higher voltages This instrument is called the "megger" and has a world-wide reputation The new instrument is called the "meg" insulation tester As its weight is only 7 lb and its dimensions are only $5\frac{1}{2} \times 7\frac{3}{4} \times 6\frac{1}{4}$ inches, it is much lighter and smaller than any similar instrument The case is made of cast aluminium, one end of which is formed of an oil-tight gear box It is always ready for use and will stand rough usage A free-wheel device protects the gear from damage and prevents the armature from being turned the wrong way At 100 rev per min it generates 500 volts, and considering its size its efficiency is most satisfactory The price is only about half the price and the weight is less than half the weight of the well-known "megger" testing set

HEATING AND VENTILATION IN PASSENGER SHIPS — With the general advance of scientific progress many of the discomforts of sea life have been eliminated Distilling ensured a plentiful supply of fresh water, electricity solved the problem of lighting, refrigeration that of food preservation The accommodation of our big ships is often and rightly described as palatial If there is any problem that has lagged behind it is that of the ventilation and heating of passenger ships, a subject which was dealt with in a paper read by Mr J L Musgrave at the Institution of Heating and Ventilating Engineers on October 11 The problem is admittedly a difficult one Not only have large numbers of passengers to be accommodated in limited spaces but the conditions of sea life change from day to day Then, too, odours from the machinery spaces, from the paintwork, store-rooms, kitchen, bathrooms, etc, have to be prevented from reaching the living spaces, and at the same time an ample supply of fresh air, heated or cooled as the case may be, has to be kept in circulation throughout dining saloons and cabins In his paper the author referred to these things and gave it as his opinion that though shipbuilding firms employ experienced men to design the ventilating and heating arrangements, the co-operation of the fully-qualified heating and ventilating engineer at an early stage of the design of the ship would lead to more satisfactory results, and that expenditure on improved ventilation would prove a profitable investment

The Hydrogen Molecule.[1]

IN Prof. Crehore's papers on the hydrogen molecule, Saha's theory of electromagnetic forces is made use of, which is founded on the Einstein relativity theory. A certain type of atom is described for hydrogen, consisting of a revolving nucleus of positive electricity with two revolving negative electrons, one on either side of the nucleus, and having a common axis of revolution with it, and it is shown that the resultant of the electrostatic and electrodynamic forces acting at points the distance of which from the atom is great, compared with the distances between the atoms in a crystal, varies inversely as the square of the distance. Gravitational force is thus shown to result from the combination of electrostatic and electrodynamic forces, when relativity is taken into account. The spinning of the positive nucleus, and of the electrons, gives them an ellipsoidal form, the ratio between the major and minor diameters being in each case 3·058. For the negative electron the major diameter is $6·514 \times 10^{-13}$ cm. and the minor is $2·130 \times 10^{-13}$ cm. The greater part of the mass of the atom resides in the positive nucleus, and, as it is assumed to be wholly of electromagnetic origin, this nucleus is extremely minute in comparison with the negative electron, as in the commonly accepted theory of atomic structure, the solar system theory.

In the hydrogen atom, when a disturbance takes place, the electrons will move a certain distance along the common axis about which they and the positive ellipsoid are rotating, away from the latter, and will then return to their original position. Crehore is of opinion that it will be possible, in this way, to account for the emission of various kinds of monochromatic light from the atom, and that the existence of definite quanta of luminous energy may be explained. He contemplates the adaptation of the whole of the mathematics of Planck and of Bohr to his special form of atom.

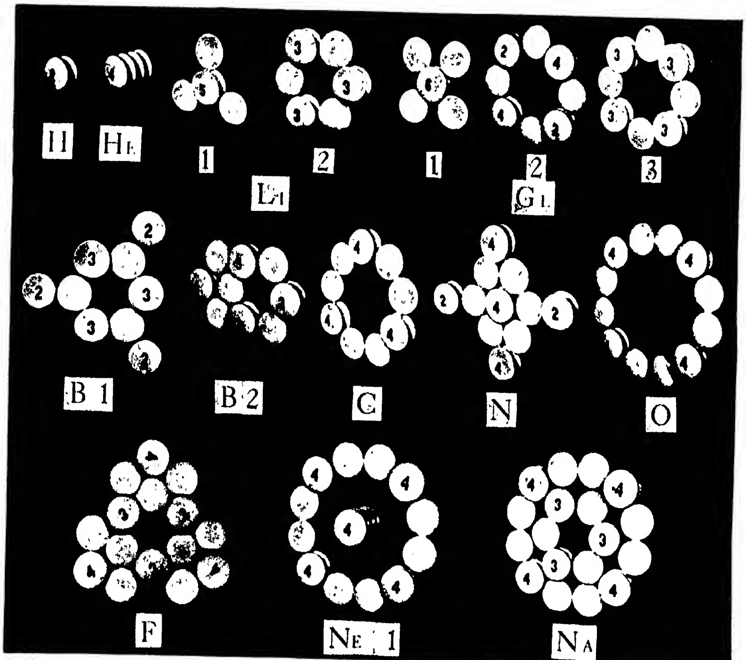

Fig. 1.—H, hydrogen atom, two coaxial, ellipsoidal electrons, on either side of positive electron with charge +e and mass 1·008. He, helium atom, four coaxial electrons with positive nucleus between them. Li 1, discarded by Crehore. Li 2, three δ particles with three binding electrons representing Li 7, N = 3. Gl 1, discarded by Crehore. Gl 2 and 3, do not represent observed isotopes. B_1 and B_2, isotopes of boron B_{10} and B_{11}. C, carbon with six binding electrons corresponding to the atomic number of the element, N = 6. O, oxygen, N = 8, eight binding electrons. F, fluorine, N = 9, nine binding electrons. Ne 1, Ne 20, the helium atom at the centre is supposed to be equivalent to an addition of two binding electrons. Na, sodium, N = 11, eleven binding electrons.

The action of one hydrogen atom upon another, at a distance from it, is investigated, with the restriction that the axes of rotation are parallel to one another. Mathematical evidence is obtained of the possibility of certain definite positions of equilibrium for the second atom, in the field of the first, so that the two are bound together to form a molecule. Their distance apart appears to be of the order of 10^{-8} cm., or enormously large, when compared with the size of the atoms. The distance is of the same order as the distances between the atoms of crystals, and it is to be supposed that similar relations to those between two hydrogen atoms, in a hydrogen molecule, exist between the atoms of sodium and chlorine, in sodium chloride, and that a number of such atoms are linked up, in

[1] Prof. A. C. Crehore, *Phil. Mag.*, Oct. 1921, May 1922, June 1922.

this way, into a large compound molecule or crystal. Crehore hopes that his theory will be found capable of explaining all the properties of matter, chemical affinity, valency, and the electric and magnetic properties

Prof Crehore has constructed a number of models consisting of wooden ellipsoids, which represent electrons, to show the structure which he assigns to the atoms of a number of elements, including several of the isotopes, which have been observed, and the atomic weights of which have been determined by Aston and Fowler, with the positive ray spectrograph Reproductions of some of these models appear in Fig 1, and they account for the observed atomic weights of the different elements, including those of the isotopes as determined by Aston and Fowler The positive nuclei do not appear in the models, as the ellipsoids of revolution representing them are very minute compared with the negative electrons. Crehore assumes the existence of three different kinds of positive nuclei, those of hydrogen, with charge $+2e$ and mass 1·008 those of helium, with charge $+4e$ and mass four, and those of a hypothetical element with charge $+3e$ and mass 2·333 In building the models these nuclei are combined with electrons as follows, to form positively charged particles, (1) that of hydrogen, with one negative electron, giving a particle H′, with charge $+e$, and marked 2 in the models to show that the charge of its nucleus is $+2e$, (2) that of helium, with two negative electrons, giving an α particle with charge $+2e$, marked 4 in the models, as the charge of its nucleus is $+4e$, (3) that of helium, with three electrons, giving a particle with charge $+e$; (4) that of the hypothetical element, with mass $2\frac{1}{3}$, together with two electrons, positive charge $+e$ and marked 3 in the models.

Calling this δ, the isotope of lithium (Li 7), with atomic weight 7, is formed by a ring of three δ particles, joined by three electrons, which may be shown developed into a straight line as $-\delta-\delta-\delta\ldots$, the full hyphens representing the binding electrons. Beryllium is assigned the structure $-4-2-4-$, the two 4 particles being joined by two electrons, and the atomic weight being nine Be 10 is a ring $-\gamma-\mathrm{H}'-\gamma-\mathrm{H}'$. Carbon is represented as $=\alpha=\alpha \quad \alpha$:′:, oxygen as $=\alpha=\alpha=\alpha=\alpha$.′. , and neon as the same ring of four α particles, with a helium atom at its centre, the common axis of the four negative electrons and one positive particle of the helium being at right angles to the plane of the ring

It will be understood that the γ particle is obtained from helium by removing one electron, and the α particle by removing another, from the other end of the axis, about which the electrons and the positive particle are regarded as rotating The H′ particle, with charge $+e$, is obtained from Crehore's hydrogen atom by removing one of the two electrons on either side of the nucleus, and the δ particle will have two electrons, one on either side of the nucleus, and rotating about its axis These α, γ, H′, and δ particles are held together by binding electrons to form the atomic models described above The atomic number is in general equal to the number of the binding electrons

---

Athletics and Oxygen Supply.

In attempting to analyse the factors which underlie muscular efficiency, most observers have been content to concern themselves with a consideration of the oxygen supply They have devoted themselves to a study of the means by which fuel arrives at the engine rather than to a study of the behaviour of the engine itself As a result of the work of Fletcher, Hopkins, and of Hill, we are now in a position to consider the broad question of athletic capacity from the details of the changes which we know take place in the contraction of a single isolated muscle

We know that during the initial contraction of the muscle and the period in which this contraction is maintained, there is a liberation of lactic acid within the muscle, and that the actual contraction of the muscle is a consequence of the physical forces called into play by the appearance of this acid at various membranes or surfaces within it The fact of great significance is that these processes in which the full force of the muscle is developed and maintained do not demand for their accomplishment any supply of oxygen whatever While the muscle relaxes the lactic acid present is neutralised by the supplies of available alkali in the tissues, but not until the period after relaxation is complete does the oxygen consumption of the muscle begin In this final stage, in which the muscle is apparently at rest, a process goes on which may be compared to the recharging of an accumulator, for not only is oxygen consumed but the lactic acid disappears and heat is developed

A little reflection is sufficient to help us to realise that the sequence of changes in the isolated single muscle, in which the oxygen consumption only occurs during the final stage, has its counterpart in the processes going on in the body of a man running a race. When the running stops, he is "out of breath," that is to say he still needs oxygen in excess of his resting requirements, for he does not, from minute to minute during the race, obtain all the oxygen necessary to oxidise the lactic acid produced in the contractions of his muscles If he runs slowly the process of removing lactic acid will be correspondingly facilitated, for his oxygen intake will be nearly sufficient to deal with all the lactic acid produced If, however, he runs quickly, while he does not increase his oxygen intake, he does increase his lactic acid production, and this production will soon outstrip its removal. In other words, the runner will become fatigued. Fatigue, then, is seen to be due, among other things, to the accumulation of lactic acid in the muscle, and the extent of a man's capacity as an athlete depends on the extent to which he can tolerate such an accumulation His toleration for lactic acid will depend on the reserve of alkali which his tissues contain for neutralisation of this acid

Prof A V. Hill, in a paper read before the Section of Physiology of the British Association at the recent meeting at Hull, was at some pains to point out the errors into which various observers have fallen by neglecting the oxygen consumption which takes place after running stops. They have assumed that the oxygen consumption per minute during the running represented the total energy requirement, and have in some cases arrived at the absurdity that quicker rates of running require less oxygen than do slower rates Yet it is precisely *because* the oxygen consumption can to a certain extent lag behind the development of energy, it is *because* the isolated muscle can exert its full strength in the absence of oxygen, that a man can run 100 yards at a much greater speed than he can run 1 mile.

An interesting confirmation of the view that fatigue is due to the accumulation of lactic acid in the muscles is obtained by considering the fact that

a man of athletic frame can "run himself out" to such an extent that he requires 10 litres of oxygen at the end of exercise above his resting consumption, he will absorb this amount during the 8-10 minutes which follow the end of the exercise. Now the amount of lactic acid which this oxygen will oxidise can be calculated, and on the assumption that a man of 70 kgm. weight is using 25 kgm. of muscle, the calculation indicates that when an athletic man is exhausted, the lactic acid present will amount to 0·33 per cent. of his muscle weight. But Meyerhof has determined that the maximum percentage of lactic acid which can be produced by stimulation in isolated mammalian muscle varies from 0·3 to 0·4 per cent. The agreement between the two figures is very striking.

The fact that a runner does not consume all the oxygen he requires for running until the exercise is over may be regarded in another light. One may say that the runner gets credit for oxygen. Let us suppose that before exhaustion he can get credit for 10 litres. Then, if during exercise he breathes in 5 litres per minute, it follows that in running for 1 minute he has energy corresponding to 15 litres of oxygen at his disposal. In running for 5 minutes, however, the energy available only corresponds to $(10 + 5 \times 5)$ 35 litres of oxygen, that is to say, it corresponds to 7 litres per minute. Roughly speaking, the energy available per minute when running 5 minutes is less than half that available when running only 1 minute.

It was found to be possible to plot a curve showing the relation of the true oxygen consumption in running various distances at a maximum rate to the time taken. The distances chosen were those of the customary flat races. It was found that the curve was of the same general type as that obtained when the speed developed in the various world's records was plotted against the time taken. In other words, it was evident that the shape of this latter curve could have been predicted from considerations of oxygen consumption.

The Fiftieth Anniversary of the Dutch Zoological Society.

THE fiftieth anniversary of the foundation of the Nederlandsche Dierkundige Vereeniging, which was celebrated at Amsterdam on September 24 and 25, was an event of much scientific interest.

At the meeting held in the large hall of the Amsterdam Zoological Gardens ("Natura magistra Artis") the president, Prof. J. F. van Bemmelen, of the University of Groningen, delivered an interesting address on the history of the Society. He referred in the course of his address to the important part the Society has played in the scientific investigation of the Dutch marine fauna and flora and in the establishment of the permanent Marine Biological Station at Helder, to the activity it has shown in the movements for the preservation and protection of native wild animals and to its association, in an advisory capacity, with Dutch Government Departments on questions concerning the scientific development and regulation of the marine and fresh-water fisheries.

At the conclusion of his address the following were admitted Honorary Members of the Society: Prof. O. Abel, Vienna; Prof. M. Caullery, Paris; Prof. L. Dollo, Brussels; Prof. B. Grassi, Rome; Prof. V. Haecker, Halle; Prof. S. J. Hickson, Manchester; Prof. N. Holmgren, Stockholm; Prof. T. H. Morgan, New York; Dr. F. Sarasin, Basle; Dr. J. Schmidt, Copenhagen.

On the following day, September 25, a large party of the members with their foreign guests set forth from Amsterdam in a steamboat through some of the most interesting and beautiful waterways of that part of the country to visit the new Fresh-water Biological Laboratory stationed in the river Vecht near Vreeland. A large and commodious houseboat called the *Meerval* has been fitted up with aquaria, dredging apparatus and other appliances for systematic and biometrical investigations of the fresh-water fauna, and there is sleeping accommodation for two or three investigators and the staff. The *Meerval* can be moved about from place to place during the summer months and is laid up for the winter at Helder.

The party was received on board the *Meerval* by Dr. Redeke, the director of the Marine Biological Station and Inspector of Fisheries, who gave an account of the investigations in progress and explained the exhibits and apparatus that were displayed.

One important result of the activities of Dr. Redeke and his assistants will be the publication of periodical reports on the fauna and flora of the Zuider Zee, and particularly of that part of it which is threatened with destruction by draining. An advanced copy of the first number of these reports was shown to the visitors.

The members of the society and their guests were entertained on the Sunday night at a banquet in Amsterdam, and on the Monday were the guests of Dr. and Mrs. Redeke at lunch at Vreeland.

It was unfortunate that Prof. Caullery (Paris), Prof. Dollo (Brussels), Prof. Grassi (Rome), Prof. Morgan (New York), and Dr. Schmidt (Copenhagen) were unable to attend the celebrations, but the foreign guests who were present thoroughly enjoyed the opportunity thus given to them by their most hospitable Dutch hosts of an interchange of views on zoological problems with friends and colleagues they had not met since pre-war days.

We may congratulate the Dutch Zoological Society on the attainment of its fiftieth anniversary, and on the valuable scientific work it has accomplished since its foundation.

Processes of Rock-Formation.

IN a long communication sent to us by Mr. J. H. Goodchild, dealing with the distribution of sodium and calcium, reference is made to Prof. J. Joly's calculation of the age of the earth from the saltness of the sea, a calculation based on the assumption that the salt in the sea has been carried there by streams and rivers and has been derived by solution from the land. In opposition to this view Mr. Goodchild suggests that, contrary to the notions held at the present day by geologists, salts pass from the ocean to the land, and are being fixed as new mineral combinations in the rocks through which they percolate. He regards sedimentary rocks, such as sandstone and shale, as unstable, and liable to admixture with one another as well as to modification by the action of soluble substances like salt and calcium carbonate. As examples of changes of this sort he points to the dolomitization of limestone, the

formation of hæmatite at and near the surface, concretions in the coal measures, and vein formations of quartz, calcite, fluorspar, and barytes.

Mr Goodchild extends this conception to the formation of metamorphic rocks, which he regards as being formed by the action of percolating solutions on unstable strata, the action of heat and pressure being an accompaniment rather than, as petrologists usually assume, the cause of the metamorphism From this position, assuming the formation of aluminium silicates at low temperatures, Mr Goodchild has no difficulty in explaining the formation of basalt and other igneous rocks as due to the local but intensive action on sedimentary rocks such as sandstone, shale, and limestone of solutions containing sodium, potassium, magnesium, and calcium. Hence where igneous rocks are found associated with sedimentary rocks Mr Goodchild regards the former not as pre-existing igneous or other rocks that have been melted by heat and injected into the sediments in a molten state, but rather as portions of the sediments that have been altered locally by interaction with one another and with percolating solutions

According to Mr Goodchild, rock-changes in temperate climates show ample evidence of the process to which he refers, but he states that these changes are best seen under tropical conditions He makes a strong plea for the representation in colour of tropical conditions of weathering, by artists imbued with a sense of mystery, as a means whereby observers in temperate climates may be brought to realise the real nature of the processes involved in metamorphism and the origin of igneous rocks

For fuller details as to Mr Goodchild's views, reference may be made to papers on "Laterization in Minas Geraes, Brazil" (Trans Inst Min Met, 1914, vol 23, p 3), and "Land Growth" (*Mining Magazine*, 1921, vol 25, p 75)

University and Educational Intelligence.

BIRMINGHAM—We recently announced in this column the appointment of Mr. K N Moss as professor of coal- and metal-mining This appointment has now been followed by the creation of a chair of petroleum-mining, to which Mr R R Thompson has been elected Prof Thompson was on the staff of the mining department of the University during the session 1911-12, since when he has had experience of oil-mining in Persia, Burma, and elsewhere He has recently been Director of Lands and Mines in Trinidad, a post which he relinquished to come to Birmingham. Sir John Cadman continues to act as honorary adviser to the mining department, and with Dr Haldane as director of Coal-mining Research, the University takes a very high place as a centre of instruction in mining in the British Empire

CAMBRIDGE—Prof H R Dean, professor of pathology, has been elected to a professorial fellowship at Trinity Hall Prof R M Dawkins, of Oxford University, formerly director of the British School at Athens, has been elected to an honorary fellowship at Emmanuel College, where he was formerly a fellow. The Master of Jesus College has been appointed to represent the University on a grand committee established to make arrangements for the commemoration next February of the bicentenary of the death of Sir Christopher Wren

Mr F G Mann, Downing College, has been appointed assistant to the professor of chemistry The Gedge Prize has been awarded to F J W. Roughton, Trinity College, for an essay on "Some Blood Gas Problems."

LONDON.—At a meeting of the Senate held on October 18, a communication was received from the Minister of Health forwarding draft heads of agreement with reference to the School of Hygiene which is to be established as a School of the University with the donation of two million dollars made for the purpose by the Rockefeller Foundation These provide for the erection of suitable buildings on a site in Bloomsbury and the constitution of a Board of Management and a Court of Governors for the control and administration of the School Resolutions were adopted expressing the concurrence of the University in the proposed scheme, and the very great satisfaction with which the Senate have learnt of the munificent contribution of the Rockefeller Foundation and of the intentions of the Government with regard to the maintenance of the School

To a communication from the Clerk of the London County Council intimating the desire of the Council that the question of the Bloomsbury site for the University should be reopened, the Vice-Chancellor was requested to reply that the Senate is prepared, "should His Majesty's Government wish to explore the possibilities of the Holland Park Site or any other site in conjunction with the University, to co-operate with the Government for that purpose"

The thanks of the Senate were accorded to the Essex County Council for a grant of 500*l* for the year 1922-1923 for distribution among the Schools of the University in the Faculties of Arts, Science, Engineering, and Economics in proportion to the number of full-time day students from that county in attendance at those Schools, also to the Stansfeld Trustees for a second donation of 10*l* for the provision of a Stansfeld lecture to be delivered on the laws and customs affecting the relationship between men and women.

The following doctorates were conferred *D Sc in Chemistry* Mr S S Bhatnagar, of University College, for a thesis entitled "Studies in Emulsions and Surface Tensions", Mr F C Toy, of University College, for a thesis entitled "Investigations of the Photographic Process", and Mr H Moore, for a thesis entitled "The Influence of Chromium on Steel," and other papers, *D Sc in Physics* Mr Snehamay Datta, of the Imperial College, Royal College of Science, for a thesis embodying the results of various researches in spectroscopy

A course of eight free public lectures on "Secretion and Internal Secretion" will be delivered by Prof Swale Vincent on November 6, 9, 13, 16, 20, 23, 27, and 30, at 5 o'clock, in the Physiology Lecture Theatre, Middlesex Hospital Medical School, Union Street, W 1 No tickets will be required.

A CONFERENCE on the report of the committee appointed by the president of the Board of Education to inquire into the position of English in the educational system of England will be held at Birkbeck College, Bream's Buildings, Chancery Lane, E C 4, on Thursday, November 2, at 4 30 The chair will be taken by Sir Cyril Jackson, chairman of the Education Committee of the London Council

THE University of Bristol Association of Alumni (London branch) has arranged to hold an inaugural dinner at La Renommée Restaurant, 52 Dean Street, Shaftesbury Avenue, London, on Monday, November 6, at 7 30 P.M. Lord Haldane is the president of this branch, and it is hoped that a large number of members of the University, both past and present, will be at this dinner The Vice-Chancellor and Mrs. Loveday have already accepted an invitation to attend.

Calendar of Industrial Pioneers.

October 29, 1874. John Laird died.—One of the chief pioneers of iron shipbuilding, Laird, who was born in Greenock in 1805, was the son of William Laird, who established a boiler-making works at Birkenhead. As a partner with his father, in 1829 he built an iron lighter of 60 tons, and in 1833 built the iron paddle steamer *Lady Lansdowne* Laird also built the first iron vessel in the Royal Navy, and in 1839 built the *Nemesis* for the East India Company, the first iron steamer to carry a gun and to steam round the Cape. The famous Birkenhead Iron Works were established by him

October 30, 1823. Edmund Cartwright died.—The inventor of the power loom, which he brought out in 1785, Cartwright was born in the Midlands in 1743, was a student of University College, Oxford, and entered the Church While holding the living of Goadby-Marwood in Leicestershire a visit to Arkwright at Matlock turned his attention to weaving, and within a year he had made the great invention by which he is remembered His loom was employed but little till the 19th century, but in 1809 he was granted a sum of 10,000*l* by Parliament Cartwright also made improvements in woolcombing and in agriculture, and assisted Fulton in some of his experiments in steam navigation

October 30, 1880. Sir Thomas Bouch died.—Born in Cumberland in 1822, Bouch was trained as a railway engineer and in 1849 became manager of the Edinburgh and Northern Railway He constructed some 300 miles of railway, instituted steam ferries on the Forth and Tay, and between 1870 and 1877 built the first Tay Bridge, nearly two miles long This bridge consisted of 85 spans, some of the wrought-iron lattice girders being 245 feet long It was completed in September 1877, and opened for traffic in May 1878 During a hurricane on the evening of December 28, 1879, the central portion with an entire train and 70 passengers fell into the Tay

October 30, 1898. Josiah Latimer Clark died. A distinguished electrical engineer, Clark began life as a chemist, and after engaging in railway work, in 1850 joined the Electric and International Telegraph Company His principal work lay in the field of submarine telegraphy and he was concerned with the laying of many cables, mainly in the East He was also an original investigator, assisted to found the Institute of Electrical Engineers, and in 1874 75 served as president

November 1, 1856. John Urpeth Rastrick died.—Trained under his father as a mechanical engineer, Rastrick took an important part in introducing railways into the country He effected improvements in locomotives, was one of the judges at the Rainhill trials of 1829 who decided in favour of Stephenson's *Rocket*, assisted Stephenson to survey the Birmingham and Manchester Railway, and with Sir John Rennie was engineer to the London and Brighton line

November 4, 1917. William Du Bois Duddell died.—Recognised as a brilliant investigator of electrical phenomena, Duddell was trained as an engineer at Colchester and then worked under Ayrton at the Central Technical College, London His discovery of the singing arc formed the starting point in the development of the Poulsen arc, while his oscillograph marked an epoch in the experimental investigation of alternating current phenomena. He was a Fellow of the Royal Society and served as president of the Röntgen Society and of the Institution of Electrical Engineers. E. C. S.

Societies and Academies.

London

Optical Society, October 12 —Prof F J Cheshire, vice-president, in the chair —L. C. **Martin** A physical study of coma A specially designed microscope objective and mounting, calculated to exhibit coma in the absence of spherical aberration and astigmatism, are described Photographs of a star image, taken when the amount of coma is equivalent to that for which the light distribution has been calculated, verify the numerical work The photometric examination of the photographic image is carried out by a special method F W **Preston** Comparison of the structure of sand blasted and ground glass surfaces Glass surfaces smoothed or "greyed" by loose abrasives in the usual way are compared with those produced by sand blasting The surfaces are practically indistinguishable either by the naked eye or the microscope and the development of the structure by etching shows that the structure is virtually identical Thus it appears that mere pounding of a glass plate can, and does, produce a surface which is structurally indistinguishable from a smoothed surface of a technical order

Paris

Academy of Sciences, September 18 M Emile Roux in the chair —L **Cuénot** and Raymond **Poisson** The development of some coaptations of insects Coaptations are defined as mechanical arrangements formed by the reciprocal adjustment of two independent parts, like a key and a lock Examples of such processes are given from *Nepa cinerea* and *Ranatra linearis* L G **Du Pasquier** The arithmetic of quaternions —Jean **Rey** The probability of illuminating an aeroplane by the beam from an electric projector —A **Sanfourche** The reactions between the gaseous oxides of nitrogen and alkaline solutions The reaction generally assumed to take place occurs only when the alkali is in excess at every point If there is any local deficiency of alkali, the gas reacts with water producing nitric acid and nitric oxide Sulphuric acid is preferable as an absorbent —Paul **Riou** The velocity of absorption of carbon dioxide by ammoniacal solutions Experimental results on the velocity of absorption of carbon dioxide by solutions of ammonium carbonate, with varying concentrations of salt and with varying temperatures P **Russo** New indications of the Trias in eastern Morocco Jean **Bathellier** The rôle of the soldiers in *Eutermes matangensis* In fighting, the soldiers of this species eject a sticky fluid, insoluble in water, which rapidly reduces their opponents to immobility If the nest is broken, the workers are protected during the process of reconstruction by a line of soldiers, which follows the contour of the gallery under repair —E **Dienert** and P. **Etrillard** The possibility of the existence of organisms in rocks capable of reviving after sterilisation by heat A repetition of some experiments by M Galippe The results of M Galippe were not confirmed the rocks were sterile after prolonged heating to 180° C

September 25 M L Maquenne in the chair —The Perpetual Secretary announced the death of M Battandier, correspondant for the section of Botany —P **Urysohn**. The ramification of the Cantorian lines —M **Seigle** The principal characteristics of mild steel bars previously broken by traction It has been generally held that a steel hardened by extension is breakable and dangerous to use Tests

on bars of mild steel broken by pulling show that this view is not exact. Details of the various tests to which the bars were submitted are given.—P. **Chevenard**: Nickel alloys retaining their rigidity over an extended temperature range. The alloy in the form of wire was heated to a constant temperature and loaded with a weight; an automatic arrangement recorded photographically the elongation as a function of the time. Curves are given for nickel, electrolytic iron, and for four alloys. A nickel-chromium-tungsten alloy was the most resistant to high temperatures.—L. J. **Simon**: The direct oxidation by oxygen or air of the esters of the alcohol acids. Methyl, ethyl, butyl, and amyl lactates when heated in a current of air undergo oxidation, giving the pyruvates in notable proportion. Ethyl glyoxylate can similarly be recognised as one of the products of oxidation by air of ethyl glycollate.—E. **Fournier**: The nature and structure of the substratum of the Jura chain. An account of the strata pierced by an experimental boring at Chazelot (near Rougemont) carried to a depth of 700 metres.—L. **Eble**: Magnetic measurements in the Paris basin. The results given for 41 stations form part of a new magnetic survey of France. The secular variation of the magnetic elements between January 1, 1896, and January 1, 1922, was practically the same for all the stations; the mean values were: declination −2° 58′, inclination −0° 32′, horizontal component +0.0014. These are almost exactly the values obtained at the central station of Val Joyeux.—Marcel **Mirande**: The influence of light on the formation of anthocyanine in the scales of the bulbs of lilies. It has been shown experimentally that the only radiations taking an active part in the reddening of the scales are those in the luminous part of the spectrum: there is a first maximum effect in the red, a much more important maximum in the indigo blue, and a minimum in the green.—L. **Berger**: The existence of an ovarian gland, homologous with the testicular interstitial gland.—J. **Carrere**: The dilator of the pupil in the selacians.—Paul **Wintrebert**: The cartilaginous pterygoid in the urodeles.

SYDNEY

Royal Society of New South Wales, September 6.—Mr. C. A. Sussmilch, president, in the chair.—R. H. **Cambage**: Acacia seedlings, Pt. VIII. A number of seedlings of different species were described. A seed of *Acacia melanoxylon* germinated after having been continuously immersed in sea water for five years. The phyllodes of various species of Acacia, such as *A. conferta*, *A. elongata*, *A. floribunda*, and *A. longifolia*, close up towards the stem at night.—M. B. **Welch**: Relationship between oil glands and oil yields in the Eucalyptus. Measurements made of the oil glands in the leaves of different Eucalypts show that the oil yield on distillation is not absolutely dependent on the number and size of the oil glands.—S. **Dodd**: Poisoning of sheep by *Solanum cinereum*. Feeding experiments proved the berries to be very poisonous. The active principle is probably solanin. Half a pound of dried ripe berries given whole were innocuous, but the same amount mashed with water caused death to sheep in six hours. The probable reason for this is that when dry and whole they passed into the rumen, where they became mixed with other food; at the end of each rumination the total amount of fruits re-swallowed was insufficient to produce poisoning. In the other case the soluble alkaloid passed direct into the digestive stomach, etc., and the amount absorbed, being lethal, death resulted.

Diary of Societies.

MONDAY, OCTOBER 30

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. Shattock: Specimens of Foreign Bodies.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—W. B. Appleton: Past and Present Methods of making Photographic Lenses.

TUESDAY, OCTOBER 31

ROYAL HORTICULTURAL SOCIETY, at 3.—C. T. Musgrave: Methods of Propagation in an Amateur's Garden.

WEDNESDAY, NOVEMBER 1

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—C. Ainsworth Mitchell: The Colorimetric Estimation of Pyrogallol, Gallotannin, and Gallic Acid.—Dr. H. E. Annett and M. N. Bose: The Estimation of Narcotine and Papaverine in Opium.—J. R. Nicholls: The Estimation of Morphine.—R. F. Morris: Further Notes on the Estimation of Potassium, by Perchlorate and Cobaltinitrite Methods.

THURSDAY, NOVEMBER 2

ROYAL SOCIETY, at 4.30.—*Probable Papers*:—Lord Rayleigh: Polarisation of the Light scattered by Mercury Vapour near the Resonance Periodicity.—Prof. G. P. Thomson: The Scattering of Hydrogen Positive Rays and the Existence of a powerful Field of Force in the Hydrogen Molecule.—H. D. Smyth: A new Method for studying Ionising Potentials.—E. Backhurst: Variation of the Intensity of reflected X-radiation with the Temperature of the Crystal.—S. Datta: The Absorption Spectrum of Potassium Vapour.—K. R. Ramanathan: The Molecular Scattering of Light in Vapours and in Liquids and its Relation to the Opalescence observed in the Critical State.

LINNEAN SOCIETY, at 5.

ROYAL COLLEGE OF PHYSICIANS, at 5.—Sir Maurice Craig: Mental Symptoms in Physical Disease (Bradshaw Lecture).

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Major A. R. Low: A Review of Airscrew and Helicopter Theory, with Aeroplane Analogies.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. P. B. Ballard: A Defence of Mental Tests.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—F. Gill: Inaugural Presidential Address.

CHEMICAL SOCIETY, at 8.—N. V. Sidgwick and W. M. Dash: The Solubility and Volatility of the Nitrobenzaldehydes.—R. H. Pickard, J. Kenyon, and H. Hunter: Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XIII. The Spatial Configuration of the Unbranched Aliphatic Chain.—J. Kenyon and R. A. M'Nicol: Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XIV. The Normal Aliphatic Ethers of *d*-β-octanol.—H. Phillips: Investigations of the Dependence of Rotatory Power on Chemical Constitution. Part XV. The Normal Aliphatic Ethers of *d*-methylbenzylcarbinol.—H. Phillips: Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XVI. A new Type of Walden Inversion.—L. Hall: Investigations on the Dependence of Rotatory Power on Chemical Constitution. Part XVII. The *di-d*-β-octyl Esters of the Acids of the General Formula $(CH_2)_n(COOH)_2$.—F. L. Pyman: Orientation of the 1:4- and 1:5-dimethylglyoxalines. Mode of Fission of a-aminoglyoxalines.—E. Light and F. L. Pyman: Bromo-derivatives of 2-methylglyoxaline.

INSTITUTION OF BRITISH FOUNDRYMEN (at Institute of Marine Engineers), at 8.—F. A. Melmoth: Notes on the Development of the Manufacture of Steel Castings.

FRIDAY, NOVEMBER 3

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir Frank Baines: Repairs to the Roof of Westminster Hall.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—F. H. Sanders: Laminated Springs.

PUBLIC LECTURES.

SATURDAY, OCTOBER 28

HORNIMAN MUSEUM (Forest Hill), at 3.30.—F. Balfour-Browne: The Life and Habits of Mason Wasps.

MONDAY, OCTOBER 30

CITY OF LONDON Y.M.C.A. (186 Aldersgate Street), at 6.—Sir William M. Bayliss: The Unity of the Human Body.

WEDNESDAY, NOVEMBER 1

UNIVERSITY COLLEGE, at 5.30.—Dr. P. Harting: Holland, the Land and its People.—S. Jones: Some Recent Results in Experimental Phonetics.

THURSDAY, NOVEMBER 2

FINSBURY TECHNICAL COLLEGE, at 4.—Prof. C. H. Desch: The Metallurgical Chemist (Streatfeild Memorial Lecture).

UNIVERSITY COLLEGE (in Physics Lecture Theatre), at 5.30.—Prof. E. G. Coker: Recent Photo-Elasticity Researches in Engineering Problems.

CITY OF LONDON Y.M.C.A. (186 Aldersgate Street), at 6.—Prof. H. Maxwell-Lefroy: How Insect Pests are tackled.

FRIDAY, NOVEMBER 3

BEDFORD COLLEGE FOR WOMEN, at 5.30.—Miss C. A. J. Skeel: Ancient Travel.

UNIVERSITY COLLEGE, at 8.—Prof. G. Dawes Hicks: The Philosophy of Religion. Succeeding Lectures on November 10, 17, 24, December 1 and 8.

SATURDAY, NOVEMBER 4

HORNIMAN MUSEUM (Forest Hill), at 3.30.—E. Lovett: The Folk-lore of the Cat.

Primitive Custom and Administration.

THE Report of the Tanganyika Territory for the year 1921, which has been issued as a White Paper (Cmd. [illegible]2), contains much matter of interest relating to native affairs It is evident that the Administration by sympathetic treatment and by a patient hearing of tribal grievances is winning the confidence of the native population, while every opportunity is being seized to remove hardships which have been inflicted on them by the excessive alienation of land under the German colonial system As a census taken in April last shows that there is a native population of 4,107,000, the responsibility for the regulation of native affairs is not light It is satisfactory, therefore, to note that a good beginning has been made towards establishing sympathetic relations with the tribes In the interests of the Territory, it is vital that the administration should be conducted with due regard to native customs and institutions It is even more important that the native should have an opportunity of development along lines in harmony with his own culture, and ultimately, it is permissible to hope, of incorporation as an essential and responsible element in the community.

In this connexion a reference in the report to native beliefs assumes a significance which might, perhaps, be overlooked. It is stated that in the Mwanza region the reigning chief has lost his authority through having failed to live up to his father's reputation as a rain-maker, and that witch-doctors are losing their hold over the younger generation These statements do more than throw an interesting light on the religious beliefs of the people. The combination of function of chief and rain-maker is not uncommon throughout Africa It is one of the marks of "the divinity that doth hedge a king" among primitive peoples Its special significance lies in the fact that not only is the person of the king or chief sacred, but his authority also rests upon his power as a sacred being, of which rain-making is one of the manifestations. The magic of the witch-doctor or medicine-man, like that of the king, is on the side of law and order, notwithstanding the, to us, sinister character of certain of his activities. Some of the great secret societies of West Africa, which are essentially religious in character, have, as one of their more important functions, the policing of their respective districts and the punishment of any transgression of the moral or social code. It follows, therefore, that any change in attitude towards the religious beliefs which form the basis of authority cannot fail to have a harmful effect on the discipline of the community. Any indication of a weakening in the regard

which the natives of Tanganyika have for the magic powers of their chiefs and witch-doctors must cause misgiving. It indicates a decay of custom which may effect the most vital elements in native culture and social organisation.

A part of the Empire far distant from Central Africa affords a striking example of a decay of custom similar to that now taking place in Tanganyika. Over the greater part of the South Seas the sacrosanct character of the chief is, or was, the basis of the whole social order. The sacred power of the chief was the sanction of the law, and in virtue of it he punished offenders. Contact with civilisation has proved fatal. The white man does not recognise the sanctity of the chief, nor does he discriminate in this respect between the chief and the ordinary members of the tribe. When he commits, without fatal consequences, acts which the native regards as tabu, the sacred character of the chief is impaired and his authority undermined. As the laws of morality, of the sanctity of married life, and of property rest on the principle of tabu, of which the chief is the supreme manifestation, not only is the authority of the chief to punish offenders questioned, but the whole social order is also disintegrated. The results can be studied in Melanesia and particularly in the New Hebrides, where contact with the white man has led to the discrediting in this way of the authority of the chief and of the elders of the community.

The social disintegration which has followed this result need not be considered here in detail. It has been detrimental to the native, and, by depleting the supply of labour, will ultimately have a serious effect on the development of the resources of the islands. Those who would pursue the subject further will find it well and impartially discussed in "Essays on the Depopulation of Melanesia,"[1] which has recently been published on behalf of the Melanesian Mission. In this instructive, and indeed valuable little book, a number of essays by missionaries, an anthropologist, and administrative officials such as Sir William Macgregor and Mr. C. M. Woodford, deal with various aspects of the question. All concur in attributing much importance to the decay of custom as a cause of the depopulation which is undoubtedly taking place in this area.

The adjustment of custom when civilised and primitive meet must inevitably give rise to difficulty. It should be the aim of the ruling power to secure this adjustment with as little harm as possible to the social organisation of the subject population. It is unnecessary to urge that certain practices cannot be tolerated under the rule of a civilised power. Human sacrifice, for example, is a case in point. It has been usual to forbid such practices entirely, as was done in the case of suttee in India. Frequently, however, total suppression entails consequences entirely unforeseen. As our knowledge of primitive peoples grows, it becomes increasingly apparent that it is difficult to interfere with one element in custom without affecting the whole. In Melanesia, head-hunting and intertribal wars have been suppressed. The results have been serious. It is not merely that these forms of activity have disappeared, but with them has gone a whole group of dependent social activities which filled the life of the Melanesian. A head-hunting expedition entailed the performance of a prolonged ritual of preparation, extending over many months, which began with the building of canoes, and included at different stages many feasts and the preparations for them. A whole group of interests, many of practical utility apart from their main object, has thus been eliminated from the lives of the natives.

The late Dr. W. H. R. Rivers, in an interesting essay which he contributed to the work mentioned above, gave it as his opinion that the most important factor contributory to the depopulation of Melanesia was psychological, and, in fact, that it was due to the lack of interest in life which followed as a consequence of the suppression of certain customs. It is interesting and significant to note, as an indication of the importance of this side of the subject, that it has led even a missionary to regret the suppression of intertribal war. It might well be worth while in such cases to endeavour, by substituting some harmless element, such as, for example, an animal instead of a human victim, to avoid total suppression of a custom embodying some objectionable features. This suggestion was put forward by Dr. Rivers, but something of the same nature is already in operation in districts in New Guinea, where the head-taking propensities of the native have been turned to account among animals which played havoc with the women's plantations.

The whole question is one of extreme difficulty and complexity. To those who realise our responsibilities to subject populations and the importance of the part the native should play in the development of tropical and subtropical lands, any suggestion of change in custom, such as that reported from Tanganyika, is big with possibilities of disaster. As a result of past experience, it is clear that each case must be dealt with on its merits and as it arises; but the general principle is equally clear that it is only by close and sympathetic study of native custom that it will be possible to avoid action which may undermine authority and destroy a social fabric upon which depends the continued existence of a primitive people.

Applied Electricity.

A Dictionary of Applied Physics. Edited by Sir Richard Glazebrook. Vol. II. *Electricity.* Pp. vii + 1104. (London: Macmillan and Co., Ltd., 1922.) 63s. net.

IT is interesting to compare the second volume of Sir Richard Glazebrook's "Dictionary of Applied Physics" with the electrical portions of older dictionaries. For example, in Barlow's "Dictionary of Pure and Applied Mathematics" (1814) it is said that "the science of electricity became a general subject of conversation" after the discovery of the "Leyden Vial." In Nichol's "Cyclopædia of the Physical Sciences" (1860) we learn that electrical science "has spoken for itself to the world as no other has." "Witness the simultaneous discovery of the Leyden Phial and the Electric shock." Three practical applications of electricity are given, namely, the lightning-conductor, the electric telegraph, and electroplating. The last is specially commended as being "so conducive to the comforts and elegancies of life." An examination of the volume under review will show how greatly our knowledge has been widened during the last sixty years. We were sorry, however, not to have seen the "Leyden Jar" mentioned.

The plan of the dictionary follows to a certain extent that adopted by Nichol, but the important sections are much larger. In fact, quite substantial books could be made of the sections written by some of the contributors. Besides the important contributions there are a few short articles and many definitions of electrical quantities, machines, instruments, and methods. The absence of an index makes it difficult to find out whether any subjects have been omitted or not. There is a very elaborate name-index, but this will be little help even to the older physicist or electrician, as many of the names will be unknown to him. We think that the younger physicist will have considerable difficulty in finding out what he wants. Doubtless, this will be remedied when the final volume is published. We have not noticed anything about electric traction, electric ship-propulsion, electric vehicles, lightning conductors, rotary and frequency converters, electrostatic machines, the attraction between electrified spheres, or the fixation of nitrogen. We take it that atmospheric electricity will come under meteorology in the next volume.

We were glad to notice that the contributors had not been handicapped by being compelled to adopt a rigid nomenclature and an invariable set of symbols. As a rule, those agreed on internationally have been adopted. Although considerable use has been made throughout of elementary vector analysis, there is little demand made on the reader's knowledge of mathematics. Academical subjects, like spherical harmonics and the perennial "electrified ellipsoid," have been omitted.

Dr. Rayner has written a useful section on alternating-current instruments and measurements. He has made a happy selection of the best modern measuring instruments. His description of the electrostatic watt-meter is specially good. Occasionally his straining after conciseness leads him into inaccuracy, as when he says (p. 11) that the torque is equal to the square of the volts instead of being merely proportional to that quantity. There is a misprint also in the equation on this page. The articles on primary batteries, accumulators, and cables are good, but the last could have been expanded with advantage. The assumption on p. 94 that the thermal emissivity is independent of the radius of the wire is certainly not true, and we doubt whether the formulæ given on p. 95 are of general application.

Mr. Albert Campbell contributes a valuable article on electrical capacity and its measurement. He generally refers to capacity as "capacitance," which is the name the Americans now use, and he calls the capacity between two conductors the "working capacity." He clearly recognises the difference between two of the various kinds of capacity and calls them by different names. In other parts of the volume, however, which capacity is meant is not so clear. For example, under units (p. 948), we read that a conductor which had a capacity of 1 farad "even though composed of plates very close together would be very large." It looks as if conductor were a misprint for condenser. The various kinds of capacities have been clearly defined by nomenclature committees of the Physical Society and of the Institution of Electrical Engineers. On p. 107 formulæ for the capacity between two circular plates and the capacity to earth of one of them are given; the formulæ are only approximations and no limitations to their accuracy are given. Their value is therefore doubtful. We note misprints in formulæ (27), (50), (54), and (55).

F. Gray's results for the dielectric strengths (now usually called the electric strengths) of air at different thicknesses are given. We think that this is a misleading way of interpreting the experimental results. If we consider spherical electrodes in air, the disruptive voltages are computed in everyday work from their distance apart and their radii, with a maximum inaccuracy of about 1 per cent. From these experiments we would conclude that the assumption that the electric strength of air was 27·4 kilovolts per cm. at 25° C. and 76 cm. pressure, whatever the thickness of the layer might be, would lead to very approxi-

mately correct results in nearly every case. We notice that the author adopts Kennelly's names for the absolute unit of electric quantity, capacity, and pressure. We thus get the abcoulomb, the abfarad and abstatfarad, and the abvolt. As they have never been recognised, even in America, by any technical society or institution, they are "technically irregular." It has to be remembered, however, that all good new names are introduced in this way.

We do not like the phrase "dielectric constant"; it surprises, at least mathematicians, to find that this "constant" varies with temperature. Many excellent methods of measuring capacity are given, but beginners would appreciate some little guidance as to which one to adopt in special cases.

Dr. Rayner's article on dielectrics will be appreciated by engineers, and Mr Melsom's article on direct-current indicating instruments will be most helpful in the test-room of every factory. Mr. F. E. Smith writes an authoritative article on systems of electrical measurements which will be of great value for reference by subsequent writers. Dr. Allmand gives a concise and excellent description of the technical applications of electrolysis. Any one reading the fascinating account of the electron theory and its application to spectrum analysis, by Sir William Bragg, will find it difficult to believe that Rutherford and Bohr's theories of the atom are not substantially correct. In his description of "electrons and the discharge tube" Dr. Crowther is also very convincing.

Mr. F. E. Smith gives an illuminating account of galvanometers, including very helpful rules for choosing a galvanometer for a particular purpose. Mr. Butterworth writes a valuable account of the formulæ used for measuring inductance and gives an excellent table for computing the mutual inductance between coaxial circles. We miss, however, his own formula and that of Mr. H. L. Curtis for computing the high-frequency inductance of parallel cylindrical wires. Mr. Campbell gives a very complete account of methods of measuring inductance and gives some 200 references to papers on the subject. The method of compensating for the inductance of a coil shown on p. 402 is not as accurate as the author states, a term having been left out in the algebraical reduction shown on this page. Mr. Dye, in "Magnetic Measurements and Properties of Materials," has produced a very complete account of modern methods.

The General Electric Company gives a very brief account of "incandescence" lamps, which is excellent so far as it goes. Most readers would like to have had further data on tungsten vacuum and gas-filled lamps. The Americans are not so reticent. We note that the temperature of the tungsten filament is about "2300° K." We take it that this is in the absolute Centigrade scale and that the K. refers to Kelvin. This is "technically irregular"; but there is a real demand by engineers and by some physicists that the absolute Centigrade scale, which is the one they use, be called the Kelvin scale, and we hope that this nomenclature will be adopted.

Prof. Honda gives a thoughtful article on the molecular theories of magnetism, and we have an account of Ewing's latest model. Dr. Chree writes a thorough and interesting account of the observational methods used in terrestrial magnetism, and Dr. Chapman describes some of the theories of terrestrial magnetism and how far the solar agent is responsible for magnetic storms and auroræ. Positive rays are described by Dr. Aston. A description is given of his mass-spectrograph and typical mass spectra are shown.

The lengthy article on radio-frequency measurements by Mr. Dye will be appreciated by workers in many research laboratories, as these methods are often of great value. We are doubtful whether it is legitimate to assume that the capacity of a coil can be represented by supposing that the coil has no capacity and that a condenser of a certain size is placed across its terminals. The formula for the high-frequency resistance of a round wire at an infinite distance away from other wires is given, but the formulæ found recently for more practical cases are not given.

Very complete accounts are given of switch-gear, telegraphy, and telephony, which will be appreciated by electrical engineers. We have only space to mention the valuable articles on vibration galvanometers, wireless telegraphy, and thermionic values, by Mr Campbell, Dr Eccles, and Prof Fortescue. Finally, the articles by Prof Richardson and Dr Wilson on thermionics, Mr Smith-Rose on the use of thermionic valves, Mr. Melsom on direct-current meters, and Dr Crowther on X-rays, are of great value.

Under units it is stated that, at the International Electrical Conference held in Paris in 1900, the Gauss was defined to be the C.G.S. unit of magnetic force, and the Maxwell was defined as the practical unit of magnetic induction. It is also stated that if we take the permeability of air to be unity and to be a pure number, the value of the Maxwell is the same as that of the Gauss. But the Maxwell is not the unit of magnetic induction density. Hence we should read in this case that a Maxwell per square centimetre is the same as the Gauss. There are several definitions of self-inductance given: that appearing on p. 727 is wrong, as the self-inductance is the linkage of the magnetic induction, and not the magnetic force, with the current. In no case is it explained how the linkages inside the conductor have to be computed. We have

noticed a few other slips and misprints. They do not appreciably detract, however, from the value of this volume, which will be welcomed by all physicists and engineers.

Spitsbergen and its Wild Life.

Amid Snowy Wastes: Wild Life on the Spitsbergen Archipelago. By Seton Gordon. Pp. xiv+206, 2 maps and 114 illustrations. (London: Cassell and Co., Ltd., 1922.) 15s. net.

ALTHOUGH the Spitsbergen Archipelago is only six hundred miles from the north pole, yet, owing to its accessibility, due to the influence of the Gulf Stream drift which reaches its western shores, it has been much visited in the summer months by naturalists and sportsmen, with the result its bird-life is better known than that of a number of continental countries. Its ornithology is encrusted in a remarkable literature dating from 1598, which comprises no less than 150 contributions, and includes Prof. Koenig's "Avifauna Spitzbergensis," which from the beauty of its meisenbach pictures of scenery, and its excellent coloured plates of birds and their eggs, is entitled to rank among the most attractive of bird-books, while its letterpress exhausts the historical aspect of the subject down to the year of its publication, 1911.

The latest expedition was organised by the University of Oxford, and visited the archipelago in the summer of 1921 under the leadership of the Rev. F. C. R. Jourdain. Mr. Gordon accompanied the party in the capacity of photographer, and hence the main attractions of his book lie in the wealth and nature of its illustrations, about one hundred in number. These are supplemented by a series of pleasantly written chapters wherein he relates his personal observations and experiences. The scientific results of the expedition, however, will appear in due course; those relating to ornithology are being prepared by Mr. Jourdain, who is an eminent authority on the subject.

The most interesting pictures and chapters of Mr. Gordon's book are devoted to the pink-footed goose, Brent goose, long-tailed duck, purple sandpiper, grey phalarope, glaucous gull, and various nesting colonies. The chief captures made by the expedition were a number of eggs of the Bernicle goose, concerning the nesting habits of which no trustworthy information was forthcoming until 1907, when the first eggs were found at Spitsbergen by Prof. Koenig. Five nests and twenty eggs were obtained in 1921, but for some unexplained reason the nest of this bird—not yet depicted—does not appear in Mr. Gordon's series, though a chapter is devoted to it.

An interesting account is given of the coal-mining

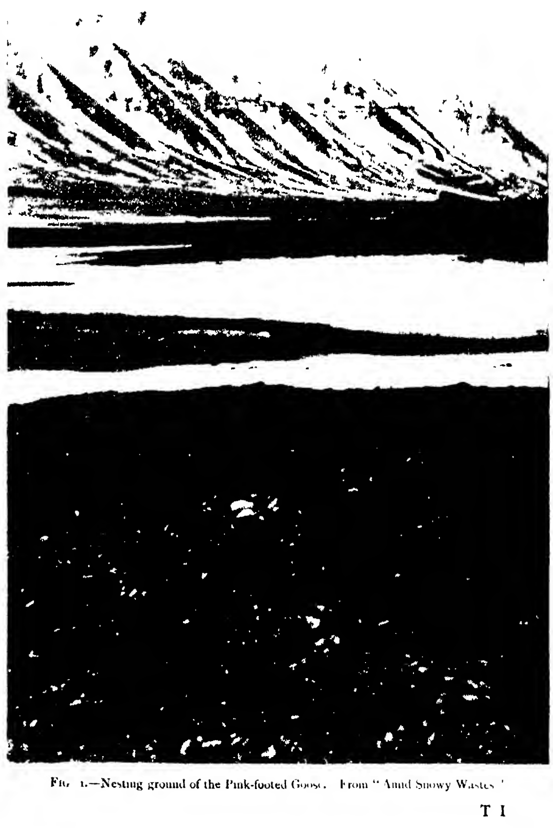

FIG. 1.—Nesting ground of the Pink-footed Goose. From "Amid Snowy Wastes."

industry, which has been developed during recent years in Spitsbergen and now finds employment for some 1300 miners, 1000 of whom, some of them with their wives and families, remain through the winter. This colonisation has effected some remarkable innovations, among others the establishment of no less than eight wireless stations whence messages may be despatched to Britain at a rate of fourpence per word !

FIG. 2.- Red-throated Diver on its nest From "Amid Snowy Wastes."

The larger mammals, such as the Polar bear, walrus, and right whale, once extremely numerous, have long ago been exterminated, and now only stragglers appear at intervals as rare waifs. The faunal changes, however, are likely to be much more rapid in the future than in the past, since there is now a considerable human population—one that will doubtless soon be considerably increased—and Spitsbergen being a no-man's-land, no protection can be imposed, and its animal life will suffer accordingly. There are three characteristic animals in the archipelago which are likely to become extinct, namely, the reindeer (*Rangifer platyrhynchus*), which is endemic, the fox (*Canis spitzbergensis*), and the ptarmigan (*Lagopus hyperboreus*). The deer, once very numerous and still unsophisticated, has been ruthlessly slaughtered in recent years. The fox since the advent of the Norwegian hunter, with his traps and poison, has been almost exterminated in places where it once occurred in hundreds. There is only one species of fox in Spitsbergen, the two species alluded to by Mr. Gordon being colour-phases due to season or age.

Special efforts were made by the expedition to find the ptarmigan, the only resident land bird, but without success, though all their likely haunts were visited, including a valley where Mr. Gordon tells us in 1920 no less than fifty brace were shot in a single afternoon by members of the Scottish Spitsbergen Syndicate. These birds must afford poor sport, for Dr. van Oordt tells us they are so tame that they can easily be killed with stones.

The eider is another bird that is rigorously and systematically persecuted. Enormous numbers of its eggs are annually taken for food and down is collected from their nests—both for sale in Norway. Mr. Gordon relates that one sloop, which had already 15,000 eggs on board, was still engaged in adding hundreds of eggs daily to the hoard. It is to be hoped that the rarer and more interesting species alluded to are also natives of the eastern isles of the Archipelago, which are so beset with ice that they are little known, and that thus they may escape extinction.

The Reopening of Europe.

Frequented Ways: A General Survey of the Land Forms, Climates, and Vegetation of Western Europe, considered in their Relation to the Life of Man; including a Detailed Study of some Typical Regions. By Dr. Marion I. Newbigin. Pp. xi+321. (London: Constable and Co., Ltd., 1922.) 15s. net.

A LARGE part of Europe is again open to the traveller. Dr. Newbigin, president of the Geographical Section of the British Association this year, does well to direct attention to the frequented ways, and her book asks those who follow them to adopt an appreciative outlook, casting off the insularity bred among our western isles. Insight into the relations of nature and man in Switzerland is not to be gained by selecting hotels where an English chaplain is on the staff. Dr. Newbigin has evidently suffered in this matter, and she remarks (p. 165) that the Catholic religion has the advantage "that no particular form of dress is imposed upon the worshippers." Her appreciation of the unconventional might have made her more tolerant (pp. 1 and 163) of "the superior person" who has been driven from anglicised Grindelwald to Japan or the New Zealand Alps. If she thinks that these fields are reserved for the prattling millionaire, let her consider Mr. Ralph Stock's exquisite little book on the voyage of "The Dream Ship" (1922), and see how the spirit of the Elizabethans may still carry our island-folk, both male and female, across the viewless seas.

Dr. Newbigin rather overlooks the value of a continuous traverse of a land-surface by the pedestrian, the cyclist, and the new users of highways that have not been so frequented since my lord and my lady took their own carriage into France. Automobilists are not always mere diffusers of dust and lubrication-odours; thousands are ready to respond to a training in history and geography. Dr. Newbigin conducts us inevitably by railway, and it may be noted that her information as to lines in the Eastern Alps is not entirely up-to-date. If, moreover, she prefers Basel, with good reason, as a place-name, why does she write Berne, St. Gothard, and the purely English Botzen, which should now, we presume, become Bolzano? She goes so far as to discuss (pp. 37 and 42) the merits of various tunnels through the mountains; these, after all, are the frequented ways. The *Gazette of the Cyclists' Touring Club* for August 1922 will show her, however, that even the Arlberg road is not forsaken. Again, in her essay on the Scottish Highlands, we should like to hear more of the pedestrian who travels across the glens as well as down them, in his attempt to realise their "relation to the life of man."

The author seems carried away at times by a certain vigour of self-expression, as if she had been caught in the swirls of "the revolt against civilisation." On p. 48 she writes, "latitude is only one of the factors which influence climate," and styles this "current geographical slang." Three pages on, she tilts against "latent heat," surely a very innocent antagonist. Again, has geographic environment moulded "the ferocious individualism of the Scot" (p. 261), which causes him to charge as much as 2s. 6d. for a belated breakfast on a winter's day? Is not this seeming lack of hospitality to be ascribed to the advent of tourists from the south, by way of Edinburgh, into the quiet of his ancestral wilds? Do we not remember how a cotter's wife was on the look-out for us one morning with a gift of oatcake, lest we should go hungry on a twenty-mile track under the Paps of Jura; or how a poor fisherman forced a tepid meal upon us, with the remark, "I should not like you to pass this house"? This is how the loneliness of moor and island have really affected the Gael of the old stock, despite the clan-animosities intensified by seclusion in the glens. Dr. Newbigin is at her best, and thus at a high level, in dealing with the influence of climate and land-forms on European vegetation. Had our military organisers known as much geography as is compressed into p. 55, the "mediterranean climate" would not have wrecked a band of gallant men sent up into the snows from Salonika.

Dr. Newbigin's photographs are a change from too familiar scenes. She gives us, for example, the vine-clad pergolas of Domo d'Ossola and the deforested slopes above La Grave. She certainly did not reach the latter spot by railway. In the Italian chapters, while seeking to be moderate, she cannot conceal a genuine hate of Venice; and, when she justly charms us with Ravenna, she elaborates a contrast that cannot be entirely sustained Did the Goths consciously embrace the creed of Ulfilas because his homoiian views provided a religion for "free men"? We are puzzled by the intricacies of p. 292, and are not going to allow so good a geographer to entrap us in the maze of Alexandrian controversy, or into a discussion of the Virgin enthroned with angels in Sant' Apollinare of Ravenna. It is more profitable to note that the explanation given (p. 231) of phenomena at the Solfatara confirms a suggestion recently made in NATURE (vol. 109, p. 559).

Dr. Newbigin's reliance on the railways leads her to call (p. 309) the Assisi–Foligno–Orte loop "an easy route" to Rome. The alluvial infilling seems to have made her forget that she is running upstream past Monte Subasio, and that clever engineering was required to get back from Spoleto by the gorge of

Narni to the Tiber. Bertarelli's "Guida itineraria del Touring Club italiano," route 180, puts the true aspect of this dissected country before the geographic tourist. Such tourists will receive much encouragement from the broad views of western lands provided in the book before us. Perhaps in another volume the author will show how intensive studies of equal value may be carried on by easy deviations from frequented ways. The piazza of Todi, 1350 feet above the sea, Foix on the Ariège, guarding one of the few passes into Spain, or Radstadt, tinkling with cattle-bells, on the high pastures of the Tauern, may serve as epitomes of their regions and of the reaction of environment on man. But Dr. Newbigin certainly does not need suggestions.

GRENVILLE A. J. COLE.

History of Astronomy.

Histoire de l'Astronomie. Par E. Doublet. (Encyclopédie scientifique.) Pp. 572. (Paris: G. Doin, 1922.) 17 francs.

IN his first chapter the author passes in review the principal works on the history of astronomy, beginning with Weidler's book and ending with the great work by Duhem on the cosmical systems. Of the valuable books of Grant and R. Wolf, only the titles are given, and several others are omitted altogether Of monographs, only Schiaparelli's first two papers are mentioned. This is natural enough, since there is plenty of evidence that the author is quite unacquainted with the rich literature of memoirs and short papers on the history of astronomy which has appeared within the last fifty years Whenever a fact is not mentioned by Delambre, Duhem, etc, it will be looked for in vain in M. Doublet's pages, and whenever fresh light has been thrown on any subject since they wrote, he is not aware of it. Take, for example, the paragraph on Hipparchus. We are told that his diopter was in the Middle Ages called a Jacob's staff, in reality the former had a cursor with a round hole in it, and was used only for measuring small angles such as the diameters of sun or moon, while the latter was shaped like a cross, with the shorter arm movable (on p. 152 the invention of the baculus is correctly attributed to Levi ben Gerson of Avignon, as Duhem had also done). The star of Hipparchus is compared to the new star of 1572, whereas there can be no doubt that it was nothing but the comet of 134 B.C. The star-catalogue of Hipparchus is said to contain 1025 stars and to have been handed down to us by Ptolemy, but it has been shown by Boll that the catalogue probably contained only about 850 stars, while it is now universally recognised that Ptolemy's catalogue is not a mere reproduction of that of Hipparchus. Next it is stated that Hipparchus put the solar parallax equal to 3'; it was Ptolemy who did that, whereas Hipparchus said that it was at most a minute and a half. On the same page we read that Hipparchus determined the principal lunar inequalities with admirable precision. Hipparchus knew only one inequality, the equation of the centre; but that is, perhaps, a slip, as it is elsewhere (p. 110) mentioned that Ptolemy discovered the evection.

The most valuable part of Duhem's work is his account of Latin astronomy in the later Middle Ages, as he was able to make use of many manuscript sources. M. Doublet has done right in quoting him largely, but here, as everywhere else, the consequences of never referring to the original sources are evident Duhem gives a very unsatisfactory account of the planetary system of Al Betrugi, which was very much discussed in the thirteenth century both at Paris and at Oxford. The account of it by M. Doublet similarly misses the most important part of the system. In the same way, the account of King Alfonso and his Tables reproduces all the old misstatements which have been refuted long ago. The tables were *not* published at the time of the King's accession, but some twenty years later, and *no* change was made in them as regards precession; they were *not* prepared by a "numerous commission," for it would have been necessary to raise the dead, since the alleged members of that Royal Commission lived long before King Alfonso's time. The "Libros del Saber" were never translated into Latin, and were quite unknown until they were at last printed some sixty years ago, and the last edition of the tables was not printed then, but in 1641

The author's account of the progress of astronomy from the end of the Middle Ages to the time of Newton does not differ much in extent or quality from the earlier chapters We have only space to direct attention to a misunderstanding on p 255, with regard to Kepler's work on Mars What produced errors of 8' was not the use of the Tychonic system (for that, of course, made no difference whatever, being merely the Copernican system with the origin of co-ordinates transferred to the earth), but the use of an excentric circle with "bisected excentricity," after the manner of Ptolemy.

Having found the first two-thirds of the book rather disappointing, we are glad to say that the chapters on French astronomers in the eighteenth and first half of the nineteenth century are very interesting and pleasant to read. They do not go into details as to the work of these astronomers, any more than do the earlier chapters, but they tell a good deal about the Cassinis, the Maraldis, etc., down to Arago and Leverrier, which will be new to most readers.

J. L. E. D.

Our Bookshelf.

How to Measure in Education. By Prof W. A McCall. Pp. xiii+416. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd, 1922.) 15s. net.

IN the work under notice an attempt is made to show that everything in education must submit to statistical measurement or be condemned as worthless. Fourteen theses in praise of measurement are blazoned in large type at the outset. One of them states, "To the extent that any goal of education is intangible it is worthless"; as this is given not only the dignity of capitals but also the embellishment of inverted commas it presumably conveys some meaning to the author. Education in this book means a few of the elements of instruction, such as reading, writing, and the mechanical parts of arithmetic and composition. An elaborate analysis is given of how to diagnose defects in reading, and ignoring the analysis, we are told that "there are more failures due to failure of interest than the world dreams of." The schoolmaster who has important tasks in education other than those of teaching mechanical elements would greatly value some help in measuring the interest of his pupils, but will ask in vain. The importance of carefully framed instructions in giving tests is rightly stressed, but we are told that such "instructions should equalize interest." To accomplish this the pupil must, apparently, be told how important it is to do well in a test. If he is retractory, or keen on other things in school besides tests, the advice may not be effective. Masters, however, are in a worse plight, for the tests are used not only to measure the pupils, but also the teaching and the teachers; and that form of measurement is said to be of most service "which does not require a previous acquaintance with the pupils"

The most valuable part of the book is that concerned with "scaling the test," as it shows the large amount of statistical treatment necessary to prepare a suitable test of skill. A useful suggestion is made for fixing a single common unit of measurement for all mental scales for elementary schools, namely, some function of the variability of pupils of twelve years. The standard deviation of pupils of sixteen years is also suggested as a unit for measuring older scholars.

The final section of the book deals with tabular, graphic, and statistical devices Each part has a useful students' bibliography, but it is strange to note the omission, in a work of this nature, of all reference to the writings of Udny Yule, from whom the student of statistical methods will derive more real help than from any of the authors quoted.

Fruit Farming: Practical and Scientific for Commercial Fruit Growers and Others By C H. Hooper. Second edition, Revised and Extended Pp xxiii+212 (London The Lockwood Press, 1921.) 6s. net.

WITHIN the limits of two hundred pages Mr. Hooper has aimed at the production of a text-book of fruit farming under English conditions. After a brief introductory section on the training of the prospective grower, he deals in succession with the capital required, the selection of suitable land, the law in relation to fruit farms and market gardens, the laying-out of plantations and orchards, and the cultural details and costings of the more important hardy fruits of this country. The later chapters are concerned largely with the more scientific aspects of the subject, such matters as soils, manuring, insect and fungoid pests, and spraying and other forms of disease-control in turn receiving attention. Also included are brief histories of many of the well-known varieties of apples, pears, plums, and cherries The numerous interesting and economically important problems relating to pollination and fertilisation and the setting of fruit are briefly considered and the author is able here to provide data from his own investigations The volume is completed by several sections dealing with special points of a purely commercial character, as, for example, the marketing of fruit and book-keeping.

Many chapters have been contributed by specialists and present in an abbreviated form the results of recent research A large part of the volume has in fact been re-written since the first edition and brought up-to-date. With these alterations and some useful additions the second edition justifies its appearance

In a work of so small a compass, which seeks to stand as a text-book of its subject, the selection of matter for inclusion calls for careful discrimination It is open to some criticism in this respect and also for occasional repetition. Printers' errors are not infrequent in certain chapters Much of the information given on economic points is not readily accessible elsewhere, and it is in this direction probably that the volume will prove to be of most service to its readers

First Lessons in Practical Biology By E W. Shann. Pp. xv+256 (London: G. Bell and Sons, Ltd., 1922) 5s

MR. SHANN's endeavour to provide a course of biology suitable for lower fifth forms, and within the means of the average school, is not entirely satisfying Rightly he relies on plants for the experimental work, and on both plants and animals, employing them in alternate chapters, for the observational. But experiments on plant physiology are not reached until chapters 16 and 17, and by that time the preceding lessons have incidentally given the very information which the experiments should surely be intended to enable the pupils to discover for themselves There are good chapters on variation and heredity, soils, insect pests, and other topics of general biological interest; but neither with plants nor with animals does the author make the best use of his material as a means of education and of training the powers of observation and reasoning If he disapproves of the heuristic method, he should at any rate indicate the evidence on which conclusions as to homologies are based, and not be content with mere statements

Apart from general considerations, sentences are in several instances faultily composed; and there is a large number of actual errors: *e g.* "false" fruits are wrongly defined; rose-hips *will* germinate without passing through the digestive tract of an animal; rose stamens are peri-, and not epigynous; *Urtica urens* has ***not*** a creeping stem, the biramous appendage is ***not*** the primitive form of crustacean appendage; the telson is ***not*** a segment; the abdomen of Blowfly does ***not*** exhibit respiratory movements; the embryo in a

seed is not simply the plumule and radicle, but includes also the cotyledons—we have not exhausted the list of inaccuracies.

Many of the illustrations are the work of boys at Oundle School and are of creditable draughtsmanship; but for teaching purposes we prefer outline with a minimum of shading in order that significant features may receive due emphasis.

The Discovery of the Circulation of the Blood. By Dr. Charles Singer. (Classics of Scientific Method.) Pp. x+80. (London: G. Bell and Sons, Ltd., 1922.) 1*s.* 6*d.* net.

THIS is the first of a new series entitled "Classics of Scientific Method," and whets our appetite for its successors. The series aims at providing in convenient form reproductions of the great masterpieces of science, together with an account of the action and re-action of ideas which, through process of time, led up to the crucial experiments carried out and described by some great master. This account of Harvey's discovery of the circulation of the blood is excellent. The first chapter, in language freed so far as is possible of technical terms, describes the structure and function of the circulatory system as we now know it—a modification of the paragraph on p. 8 dealing with the relation of carbon dioxide and hæmoglobin seems desirable—and contains a clear diagram. The subsequent chapters set forth in words and by illustrations the ideas held by the ancients regarding the vascular system, and how the Renaissance of the fifteenth century and the work of such men as Leonardo da Vinci, Servetus, and others, culminated in Harvey's great discovery, of which a detailed and most interesting account is given.

Laboratory Exercises in Inorganic Chemistry. By Prof. J. F. Norris and Prof. K. L. Mark. (International Chemical Series.) Pp. x+548 (every second page blank). (London: McGraw-Hill Publishing Co., Ltd., 1922.) 10*s.* net.

THE first question which must be considered in connexion with a book of this kind is the class of students for whom it is intended. The preface indicates that it contains a first year's course for students who have had "a good training in chemistry in the high school." It is unsuitable for such students in England, as many of the experiments would already have been done at school, and many of the remainder would be regarded as too difficult for Intermediate students. The "International" character of the book is therefore open to question. Although the book is not suitable as a students' manual in English colleges, it should be very useful in suggesting experiments to teachers, both for lectures and for laboratory work. Many of the directions are given in unnecessary detail for students of average intelligence: how to light a Bunsen burner, for example, and there is a good deal of repetition. The blank pages are included in the pagination.

A Text-book of Organic Chemistry. By Dr. A. Bernthsen. New edition, revised to date, by Prof. J. J. Sudborough. Pp. xvi+908. (London and Glasgow: Blackie and Son, Ltd., 1922.) 12*s.* 6*d.* net.

BERNTHSEN'S text-book, in its English translation, has proved of great value to students. It is therefore satisfactory to note that the new English edition has been carefully revised and large sections dealing with important recent advances in the science added, as well as numerous small supplementary paragraphs in the old text. For a book of this character the minor errors noted are surprisingly few, and are obvious to the reader. One important omission may be noted: on p. 78 it is stated that methyl alcohol "acts as an intoxicant like ethyl alcohol," without a word as to the very deleterious physiological action of methyl alcohol. The printing and get-up are excellent, but the binding is too weak for students' use. The moderate price of the book, as well as the clear and accurate character of its contents, will ensure its continued popularity among students. The very full references to physical properties make it also a handy book of reference in the laboratory.

Plumbers' Handbook. By Samuel Edward Dibble. Pp. ix+629. (New York and London: McGraw-Hill Book Co., Inc., 1922.) 20*s.*

THE author of this handbook has had the co-operation of several well-known American professional men, and the result is a very valuable compendium relating to plumbing, sanitary arrangements, gas-fitting, heating, etc. The book is equally suitable for the practical man engaged in carrying out schemes, and the student who is learning his business. Of special interest to the British reader is Section 14, dealing with codes, or byelaws, as we should call them. These are extremely suggestive, and if carried out systematically in the United States will excite the envy of many British workers who have still to endure primitive sanitary conveniences. There is so much of value in this section that it is impossible to quote any of the points in a short review.

Science is not neglected in this volume, and there are sections dealing with metallurgy and chemistry. There is also a section on elementary mathematics; we think that the arithmetical rule for cube root (p. 511) might have been omitted, especially as logarithms are dealt with on pp. 508 and 509. The book can be strongly recommended to all connected with sanitation.

Diptera Danica: Genera and Species of Flies hitherto found in Denmark. By William Lundbeck. Part VI. *Pipunculidæ and Phoridæ.* Pp. 447+137 text-figs. and index. (Copenhagen: G. E. C. Gad; London: Wheldon and Wesley, Ltd., 1922.)

ALL students of the order Diptera will welcome the continuance of this wholly admirable treatise. It is a model of what a faunistic work should be and, unlike so many volumes of a similar nature, it also includes a useful summary of existing knowledge of the metamorphoses and habits of the insects with which it deals. The author has also wisely added the dates of capture of the various species: elementary facts of this kind are so often omitted from faunistic works that the reader is usually left with no idea as to when a particular species is likely to be met with. Of the two families dealt with in the volume before us, the Pipunculidæ include 25 Danish species out of about 75 palæarctic representatives, and the Phoridæ include 210 Danish species out of a total of about 335 from the whole of Europe. The work is well printed, clearly illustrated, and written in excellent English.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

Action of Cutting Tools.

PROF. F. G. COKER has been good enough to send me a copy of his paper on the above subject, together with the discussion which followed its reading before the Institution of Mechanical Engineers. I will (with your permission) take this opportunity of thanking him and of adding a few remarks to my letter to NATURE of August 26 of this year.

I had not, when that letter was written, a copy of the Proc. R.S. paper of 1881 at hand, and was not certain as to how far the experimental processes preceding its production were described. On re-reading, however, I see that the experimental part was omitted, and I may here state that the force on the tool was measured by a dynamometer of the type shown diagrammatically in Fig. 1, and that it was found that for cuts of similar section the force required was very nearly proportional to the cross-section of the strip removed. This of course is equivalent to the statement that the same amount of work will remove the same volume of material whether the shavings are thick or thin, provided that they are similar.

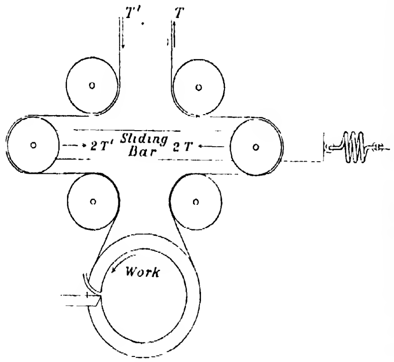

FIG. 1.—Diagrammatic sketch to show the action of dynamometer used for measuring the force on tool, T and T′ being the tensions of the two parts of the driving belt. The force acting on the sliding bar is 2(T–T′). This is balanced by the extension of the spring. Hence the movement of the bar, in conjunction with the known diameter of the work, gives (when corrected for the friction of the pulley, etc.) a measure of the force acting on the tool.

This dynamometer, which recorded the force automatically on paper moving with a velocity proportional to that of the cut, worked satisfactorily when the cutting speed was suitably chosen, though I should not use the same pattern were I again to embark on such investigations.

The materials on which the experiments were made included, besides the ordinary metals, others easier to deal with in a lathe worked by foot, and of these clay was found to be the most useful, for, according to the state of dryness to which it was brought, its behaviour under the action of the tool could be made to resemble that of any sort of metal, hard or soft, and at the same time cuts of easily measurable thickness could be taken with comparatively small forces.

While referring to the subject of material, I may mention a matter which seemed to me rather surprising. I wished to see whether it would be possible to face up a speculum casting in the lathe in order to save time in the preliminary grinding. Speculum metal, as is well known, is very brittle, but by taking a broad cut of extreme thinness with a dead-hard steel tool, continuous shavings were produced which looked like ribbons of grey satin. It was only while the edge of the tool was perfect that the cut was satisfactory, and this condition rarely lasted long enough to cover a speculum two inches in diameter.

With regard to Prof. Coker's paper, the only objection I have to make is that it has no reference to the action of cutting tools. The polarised-interference bands are evidence of elastic strain. They might be maintained indefinitely when the tool was stationary if the applied force was just insufficient to produce further rupture, and would disappear when that force was removed.

The elastic deformation, though interesting, has nothing to do with the special action of the tool, the essential function of which is to cause destructive strain throughout a small region near its edge while having no permanent effect on the body of the work.

The real interest in the action of a cutting tool is confined to the plane AB (Fig. 2) along which destructive shear takes place and a very short length of the material which forms the shaving—together with that part of the tool in contact with it.

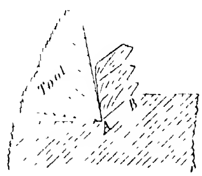

FIG. 2.—Action of a cutting tool, showing the principal and secondary planes of cleavage.

The internal structure of a shaving closely resembles that of slate, the principal plane of cleavage being parallel to AB of Fig. 2, and the angle which this plane makes with the direction of the cut is modified by, and may be said to depend on, the angle which the face of the tool makes with the same direction and the mutual coefficient of friction between the tool and the material on which it operates.

The action of the tool is always discontinuous and quasi-periodic, the period being determined by the travel required to extend the destructive shear from A to B. The period, therefore, is proportional (among other things) to the depth of the cut.

From this it may be seen that, in addition to the principal planes of cleavage, secondary and slightly differently inclined cleavages occur before the shearing across AB is complete. This was well shown in the polished and etched sections[1] referred to in the 1881 paper, and can also be recognised in the accompanying photographs (Figs. 3 and 4), though not quite so clearly.

The normal force on the tool during each period tends to expand (like rivet heads) the base of the strata which press against it, and this action causes the shaving to curl. The frictional force (parallel to the face of the tool) tends, on the other hand, to drag the base of strata towards the cutting edge, and thus to keep the shaving straight.

The shape of the cross-sections of a shaving is often rather peculiar, but is a definite function of the shape of the tool and of the properties of the material from

[1] The earliest application of "etching" for the purpose of rendering the structure of a metal visible was, I suppose, the "crowning" of twisted gun-barrels, etc.

which it is cut. It may be defined shortly as the *projection on the plane of the section of the line bounding the area of destructive shear*. This line will be in advance of the face of the tool by a distance

FIG. .

FIG. 4

FIG. 3.—Shaving from a block of paraffin. At the temperature at which the cut took place, the paraffin behaves much like a sample of cast iron.

FIG. 4.—Longitudinal section of a similar shaving. The paraffin shaving was embedded in soap, sectioned in a microtome, and mounted in castor oil.

proportional to the thickness of the cut at the point under consideration (see Fig. 5).

The shaving is always shorter than the length of the cut from which it was taken, and if α and β are respectively the angles which the principal plane of cleavage and the face of the tool make with the normal to the surface of the cut, it is easy to see that the ratio of the lengths is $\cos\alpha/\sin(\alpha+\beta)$.

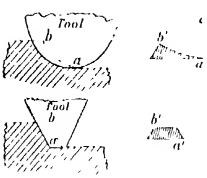

FIG. 5.—Relation between the cross-section of the cut, *ab*, and that of the shaving produced, *a'b'*.

Lubrication has an extraordinary effect in the cutting of certain materials. With brass and gun-metals no lubrication is required, but for steel, and also for such metals as soft copper and pure aluminium, clean cutting is impossible without it. Glass cutting with steel tools also requires a lubricant, for which purpose turpentine or petroleum are generally chosen.

I remember, in a correspondence with Sir G. G. Stokes on this subject, mentioning that even the presence of turpentine vapour had a noticeable effect. There can, I think, be little doubt that films of lubricant (of molecular thickness it may be) pass not only over the active part of the tool, but also penetrate along the planes of cleavage in the shaving itself.

A. MALLOCK.

9 Baring Crescent, Exeter.

One Possible Cause for Atmospheric Electric Phenomena: A Reply.

IF Sir Oliver Lodge will turn up his copy of NATURE for January 21, 1904 (Vol. 69, p. 270), he will find that I made there the identical suggestion for the origin of the earth's negative charge which he makes in NATURE of October 14, p. 512. The explanation is, however, unsatisfactory for a number of reasons, the chief of which may be stated shortly as follows:

To maintain the current from the earth into the atmosphere, it would be necessary for 2000 negative electrons to be shot into each square centimetre of the earth's surface every second. But beta rays ionise the air through which they pass, and according to recent theoretical work it appears that beta rays, no matter what their velocity may be, produce more than 40 pairs of ions along each centimetre of their path in air at atmospheric pressure. Thus in each cubic centimetre of air near the earth's surface 80,000 pairs of ions would be produced per second. But we know from actual measurements extending from the equator to the polar regions that only 4 or 5 are so produced and all these can be accounted for by known radiations.

Sir Oliver suggests that "the beta particles would be magnetically inveigled towards the poles, where they might descend with down currents." This suggestion has been made previously, and it is easy to show that it offers no way out of the difficulty, although the demonstration is too long to be given here.

G. C. SIMPSON.

The Green Ray at Sunset and Sunrise.

IN NATURE of October 14, p. 513, Prof. Alfred Porter maintains that there are two distinct phenomena which go under the name of the green flash, and that the one most usually seen is an after image in an eye fatigued by the red light of the sun. I have seen the green ray many times in this country and in the tropics, and the phenomenon as I have seen it is always exactly the same; I am quite convinced in my own mind that it is not due to eye fatigue, for the appearance at sunrise is precisely the same as that at sunset. I have seen it a number of times at sunrise, and the first time I ever saw it was at sunrise when I was not looking out for it. I have, moreover, examined the setting sun with binoculars and with a telescope, when the sun has very nearly set, but before the appearance of the green ray proper, the upper edge has a very irregular shape owing to refraction effects, sometimes resembling flames; the tops of these "flames" gradually become bright green and the colour spreads downwards till the whole of the minute remaining part of the disc becomes green. To any one who has examined the green ray with a telescope at sunset, and has seen it with the naked eye at sunrise, it seems inconceivable that it can be due to eye fatigue.

C. J. P. CAVE.

Stoner Hill, Petersfield,
October 21.

As the green segment continues to be debated, permit me to put a few facts on record. I have often in Egypt watched the sunrise light descending the western hills, and when the edge of the shadow reached me, turned to view the sun. The first appearance of the sun is a blue segment, changing to green, and then to white. This is exactly the converse of the colours of the sunset segment; as the rising light cannot be due to an after-image, no more is the setting light. Moreover I have never seen the green light shift about, as an after-image does, by movement of the eye; it is always exactly on the segment.

Further, I often have protracted the sunset blue by walking up a slope, and so keeping it in view, on and off, as long as I go upward. The least distance

of horizon that is effective is about two miles, at which the change of colour is just visible. The "second phenomenon" of Prof. Porter is the only one which I have seen with open eyes.

W. M. FLINDERS PETRIE.

A Broadcast "Rainbow."

ON Friday, September 16, I witnessed an atmospheric phenomenon sufficiently unusual, I believe, to merit a record. Standing on Ogmore Down near Bridgend in this county (Glamorgan) at 2.30 P.M. and looking northwards across the broad vale towards the Maesteg hills, there appeared to me a broadcast rainbow colouring, stretching east and west for several miles along the vale. The day was exceptionally fine, with brilliant visibility and no trace of mist. The clouds were small and scattered, with a distant bank of cumulus beyond the hills, while the colours were clear and unmistakable, covering, from red in the west to blue in the east, an angle of about fifty degrees. The height of my point of view was about 300 ft. above the sea, and the whole apparition hung, like a veil of pure, immaterial colour, at about the level of my eyes, covering the distant hills but without screening their smallest particular. Colour Observations of the Moon.

I WISH to place on record a few observations I have made of the lunar surface seen through colour filters, which point to the presence of coloured light of various shades reflected from different parts of the moon.

The light values of various points of the moon's surface were fixed by means of a photometer shaded by colour-screens, corresponding to similar screens fixed to the eye-piece of the telescope.

Owing to the two different sources of light, electric light in one case and the lunar rays in the other, and also owing to atmospheric changes, the two sets of filters had to vary considerably in colour, in order to produce the identical colour impression on the eye.

For the telescopic eye-piece I used the following colour screens throughout these observations:

1. Red of approx. 6563 "Tenth-metre" wave length (absorbing practically all but red rays and a little yellow).
2. Green " 5173 wave length (absorbing all but green and blue rays).
3. Violet " 4120 wave length (only absorbing yellow rays).

For the photometer I used varying colours (according to atmospheric conditions), averaging

1a of approx. 6120 wave length
2a " 5922 "
3a " 4530 "

The area examined was the vicinity of Clavius. I determined the light value of the brightest spot in the neighbourhood (A) through the three screens, and in the same way a number of other spots: B, the eastern inside wall of Clavius; C and D, the floor of the crater plain; E, the great valley to the west of Clavius; F, the southern slopes of Magnus.

The result of the two observations, No. I on August 31, No. II on October 1, 1922, was as follows, reducing the figures to percentages, the brightest spot (A) being taken as 100 per cent. in each case:

	A	B	C	D	E	F	
Red screen	100%	I 16.0 II 9.1	I 1[illegible] II 0.66	I 3.6 II 0.85	I 10.0 II [illegible]2	I 15.7 II 9.1	% %
Green screen	100%	I 1[illegible] II 22	I 0.[illegible] II 0.[illegible]	I [illegible]3 II 0.16	I 11.0 II [illegible]	I 19.0 II 2[illegible].2	% %
Violet screen	100%	I 30.0 II 5.1	I 3.3 II 1.7	I [illegible] II [illegible]	I 15.0 II [illegible]8	I 21.1 II 5.1	% %

In examining the above list it will be noticed that there is a discrepancy regarding the point B, which may be due to the dazzling brilliancy of this area during the first observation. All the remaining figures, however, agree remarkably well, considering the extreme simplicity of the instruments I employed.

The experiments tend to show that (1) the floor of Clavius (also of Longomontanus, which I observed on October 1) is of a mauve colour. These areas may be basaltic and not unlike some Hawaiian crater plains of solid lavas. (2) The Terra Photographica to the west of Clavius has most probably a mottled surface of brown areas on a blue background such as copper sulphate. (3) The southern slopes of Magnus are intense green, probably streaked with areas of the same substance and colour of the crater valleys recorded.

It would be of great interest to survey accurately in this manner districts such as the crater Linné. Later tests would then clearly show if any change could be recorded in these debated areas, at least so far as coloration is concerned. A. F. WAKIH.

The Local Handbook of the British Association.

IN NATURE of October 21, p. 530, a reviewer states that "the ideal handbook in connexion with the annual visits of the British Association has yet to be written." A Committee of the Association might well be appointed to draw up a scheme. Meanwhile, I venture to offer the following suggestions:

1. The book should above all be portable, and for this purpose it should be divided into separate pamphlets, each tucked under a separate tape in a cloth-covered binding, common to the series. One could then select one's pamphlet and leave the rest in one's hotel.

2. Every handbook should have a complete index for facilitating rapid consultation.

3. There should be a map of the district on the half-inch or quarter-inch scale.

4. There should be a geological map.

5. The compilers should take a lesson from Baedeker and give practical details: population, railway stations, hotels, cab-fares, post office; short list of the chief features: museums, art galleries, libraries, churches of architectural interest, and other guide-book information in two or three pages, with street in which situated, times of opening, etc., with an asterisk indicating the most noteworthy.

6. Unless the handbook can be sent by post in advance to members (they might pay the postage) it is of little use writing long-winded articles, as visitors—attending sections in the morning, scientific excursions in the afternoon, and addresses in the evening—have no time to read them. BERNARD HOBSON.

The Early History of the Land Flora.[1]

By Dr. D. H. SCOTT, F.R.S.

I.

IN these articles the "Early History" of the land flora is understood to cover the Devonian and Lower Carboniferous periods. Before the beginning of the Devonian the records of land plants are too scanty and doubtful to demand much consideration; on the other hand, the flora of the Upper Carboniferous is so rich and so well known that to include it would unduly extend the limits of this brief survey.

Concerning the question of the beginnings of a land flora, the position has wholly changed of late, owing chiefly to the Rhynie discoveries. A few years ago we had no clear knowledge of any early Devonian plants, and such imperfect data as we possessed were commonly ignored or discredited. Nothing definite was known of any really simple fossil land plants; it could even be asserted that the Devonian plants, though different in many ways from those of the present day, were about on the same general level of organisation.

Now we have learnt, from the Rhynie investigations, that, in the earlier Devonian flora, plants existed of quite surprising simplicity, with a mere thallus, leafless and rootless, like that of some very ordinary seaweed, but yet vascular in structure, and obviously adapted to sub-aerial conditions.

The crude simplicity of some of the Rhynie plants even suggested the question whether we might not at last be on the track of the original transmigrants from the sea, of those Thalassiophyta whose conquest of the land has been so vividly pictured by Dr. Church.[2] No doubt, the Devonian period was altogether too late for the transmigration he describes, but still some of the plants then living might have retained transmigrant characters.

The Rhynie fossils are now fairly well known to the botanical reader, and it is perhaps less necessary to insist on their importance than to suggest a warning that we may possibly expect too much from them.

The flora is extremely limited and local; our knowledge of the plants, owing to the unsurpassed skill and judgment with which they have been worked out by Dr. Kidston and Prof. Lang,[3] is exceptionally perfect, but there are very few of them and they are all from one old peat-bed.

We may shortly recapitulate the leading facts. The Rhynie species of vascular plants are four in number: *Rhynia Gwynne-Vaughani*, *R. major*, *Hornea Lignieri*, and *Asteroxylon Mackiei*. Rhynia and Hornea constitute the family Rhyniaceæ, remarkable for its extreme simplicity of structure; Asteroxylon is a much higher plant, and is placed in a distinct family.

Both the Rhynias are rootless and leafless plants, with a branched underground rhizome, and a vertical aerial stem, also branched; the whole plant was eight inches or more in height. On the rhizome there are absorbent hairs, while the aerial stem possesses a few perfectly typical stomata. Otherwise there is little differentiation between the subterranean and subaerial parts. The whole may be called, without hesitation, a thallus. Both stem and rhizome are traversed by an extremely simple vascular strand.

Rhynia major is considerably the larger plant of the two, but *R. Gwynne-Vaughani* is somewhat the more differentiated, for its aerial stem is studded with hemispherical outgrowths, from which, in some cases, additional branches arose, and often became detached, serving no doubt as a means of propagation. Both outgrowths and adventitious branches are absent from *R. major*, where the stem is merely forked.

It was at one time supposed that the outgrowths of *R. Gwynne-Vaughani* might represent very rudimentary leaves, but later observations have shown that they were developed late in life, usually in connexion with the stomata, and thus formed no part of the original equipment of the plant. They may even have been traumatic in origin.

The reproductive organs are spore-sacs (sporangia) borne on the ends of branches. In *R. major* the sporangia are large—nearly half an inch long; they have a fairly complicated wall, and are filled with well-preserved spores, often still grouped in fours, and in all respects like those of the Higher Cryptogams now living.

The second genus, Hornea, has a tuberous rhizome comparable to the protocorm often found in young Club-mosses, but the stem is like that of *Rhynia major*, on a smaller scale, and just as simple. The sporangia are the most remarkable feature; they are terminal on the branches, as in Rhynia, but in Hornea each spore-sac has a central column of sterile tissue (the columella), over-arched by the spore-bearing layer, exactly as in the capsule of the Bog-Moss, Sphagnum, at the present day. This moss-like feature is very suggestive and has given rise to a good deal of speculation. Another peculiarity of the spore-sac is that its walls are scarcely differentiated from the ordinary tissues of the branch, and that where the branch forks the sporangium forks too. Here, then, it is evident that the sporangium is not an organ *sui generis*, as modern botanists have generally taught, but just the end of a branch, set apart for spore-production.

The Sphagnum-like structure of the spore-sac in Hornea is not without analogy, for just before the Rhynie discoveries, Halle had described, from the Lower Devonian of Norway, a fossil which he named Sporogonites. This is remarkably like the stalked capsule of a Moss in external appearance, and internally (though imperfectly preserved) it proved to have a columella of the same form as that subsequently observed in Hornea. Thus the Rhyniaceæ are not only the simplest vascular plants known; they likewise suggest analogies with the Bryophytes. They have in fact been placed by different botanists in three different sub-kingdoms: in the Pteridophytes, the Thallophytes, and the Bryophytes, on grounds which will be evident from the facts already given. Possibly they may represent a basal group, related at once to the Vascular Cryptogams and the Moss phylum, while at the same time retaining some of the old characters of an Algal stock. But we cannot regard so interesting

[1] Based on a course of lectures given last spring at University College (University of London).

[2] A. H. Church, "The Thalassiophyta and the Sub-aerial Transmigration," Oxford Botanical Memoirs, III, 1919.

[3] Kidston and Lang, "On Old Red Sandstone Plants, showing Structure, from the Rhynie Chert bed, Aberdeenshire," Transactions of the Royal Soc. of Edinburgh, Part I, vol. 51, 1917; Parts II and III, vol. 52, 1920; Parts IV and V, vol. 52, 1921.

a conclusion as established until we are satisfied that the surprisingly simple organisation of the Rhyniaceæ was really primitive.

We can scarcely feel sure that a certain amount of reduction may not have already been undergone, even by this early race of land-plants. The presence of stomata of the familiar type proves that the plants must long have been adapted to a sub-aerial life; at the same time the small number of these organs suggests xerophytic modification, which is quite consistent with a peat-habitat. In fact the habitat warns us that the Rhynie plants may not have been quite typical representatives of the flora of their time. A comparison with the Saltwort (Salicornia) of our mud-flats has even been suggested.[1] Such a plant, however, bears obvious marks of reduction which are wanting in the Rhyniaceæ.

We can do no more than leave the question open. Probably we are justified in accepting Rhynia and Hornea as members of a relatively primitive race, even though their excessive simplicity may have been in some part due to the peculiar conditions under which they had to live.

The presence of Asteroxylon in the same beds might perhaps be taken as an argument against the theory of reduction, for Asteroxylon was, comparatively speaking, a highly organised plant. It is true it had no roots, but the branched aerial stem was well clothed with leaves, and had very much the habit of a Club-Moss (Lycopodium). The anatomy of the stem was also quite complex compared with that of the Rhyniaceæ, though the rhizome was as simple as theirs, and, oddly enough, bore no hairs. Asteroxylon was a larger plant than the others, and had nothing specially primitive in its external aspect. The leaves were peculiar, however, in having a very imperfect vascular supply, for the strand which ran out from the central stele towards each leaf stopped short in the leaf-base and never entered the blade. This is one of three points which suggest a certain degree of possibly primitive simplicity, the other two being the absence of differentiated roots and the structure of the water-conducting elements (tracheides). Though the wood is well developed and rather complex in form, having a stellate transverse section, all the tracheides are of one kind, namely, spiral.

Unfortunately, our knowledge of Asteroxylon is not quite so satisfactory as in the previous cases, for the fructification has never been found in connexion with the plant. There are peculiar naked branches closely associated with a few of the specimens, and with these branches, again, sporangia are found in association. The sporangia are quite different from those of the Rhyniaceæ, but recall the fructification of some of the Carboniferous ferns. If we assume that the naked branches and the sporangia belonged to the Asteroxylon we get a very remarkable combination of characters, as pointed out by Kidston and Lang. While the anatomy and morphology of the vegetative organs are suggestive of Psilotaceæ (a small tropical and subtropical family, of uncertain affinities) and Lycopods, the supposed fertile branches and sporangia would link the plant to the ferns. We cannot, however, lay much stress on this surprising synthesis of diverse characters until the connexion of the parts has been established. At present there is no evidence beyond intimate association.

Kidston and Lang are inclined to identify Asteroxylon with Thursophyton, a Middle Devonian plant, of Club-Moss-like habit, hitherto only known from impressions. The fructification assigned by certain writers to species of Thursophyton is, however, of a Lycopodiaceous character, and totally different from that attributed to Asteroxylon.

Asteroxylon is included, together with the Rhyniaceæ, in the class Psilophytales, of which Sir William Dawson's genus Psilophyton, established in the 'fifties of the last century, is the type. There is now no doubt that Dawson's account of Psilophyton, so long discredited, was substantially correct. The plant had a branched rhizome and a forked upright stem, more or less spiny. The fructification consisted of long terminal spore-sacs, much like those of Rhynia. The morphological nature of the spines is disputed; they may be interpreted as rudimentary leaves or as mere outgrowths, like those of *Rhynia Gwynne-Vaughani*. A general affinity between Dawson's plant and the Rhynie fossils is evident, but the exact relations remain doubtful. The late Dr Arber regarded Psilophyton as identical with Rhynia; Kidston and Lang, on the other hand, have decided to place it in the same family with Asteroxylon. Neither view is established.

It may be mentioned that a possible Psilophyton has recently been recorded by Prof. Halle from the Silurian (Lower Ludlow) of Gothland, an interesting discovery, if confirmed.

Many plants besides the four species of Vasculares were found at Rhynie. The most interesting is a specimen of Nematophycus (or Nematophyton), a genus hitherto generally regarded as belonging to the Algæ; it has a complex structure of interwoven filaments, and some of the species, from other localities, attained a gigantic size. It is very remarkable that a plant with the structure of a highly organised seaweed should occur in a purely terrestrial flora like that of the Rhynie chert-bed. It may suggest that the Algæ of the period were doing a little transmigration on their own account.

A number of genera of the early Devonian flora have been recorded as impressions, showing little or nothing of the internal structure. Space forbids our describing them here. Some are much like Psilophyton, others resemble Club-mosses, while others again have a curiously Alga-like habit. An excellent summary of our knowledge of the Devonian plants generally will be found in Dr. Arber's little volume.[4]

The earlier (Lower and Middle) Devonian flora was for the most part characterised by comparatively simple types of land plants; in some cases, as we have seen their simplicity was extreme. Even then, however, there is evidence that very much higher forms existed. Thus the fossil known as *Palaeopitys Milleri*, from the Middle Old Red Sandstone of Cromarty, was described by its discoverer, Hugh Miller, as a "Coniferous tree," and really has the structure of a well-organised Gymnosperm. Miller himself fully realised the importance of his discovery, which has scarcely received the attention from botanists which it deserves.[5]

(To be continued.)

Solar Radiation and its Changes.[1]

WHEN one reflects upon the wide knowledge gained by astronomers concerning stellar and nebular radiation and variability, it at first seems surprising that variation in the visible radiation emitted by the sun has been discovered only recently and with much difficulty. Not until the second decade of this century could the fact be regarded as established, as a consequence of simultaneous determinations of the "solar constant" made by the staff of the Astrophysical Observatory of the Smithsonian Institution, at two stations so widely separated as Bassour in Algeria and Mount Wilson in California. The solar constant is, of course, the estimated value of the intensity of total solar radiation, in calories per square centimetre per minute, at a point just outside the earth's atmosphere, *i.e.* before suffering absorption in transmission to the earth's surface.

The main difficulty arises from the necessity of making practically absolute determinations of the solar constant, because the sun's proximity to us renders it sufficiently unique and solitary in the daylight sky to prevent that comparison with many and similar neighbours which is the foundation of our knowledge of stellar variability. No real progress towards such knowledge regarding the sun could be made until it became possible to determine and allow for the radiation absorbed in the earth's atmosphere. Failing this, even long series of simultaneous observations of the changes in the solar radiation, as received at different points on the earth's surface, are of little use, because any features common to two stations may arise from some common terrestrial cause. A striking example of this was recorded by the Smithsonian observers during the fifty days on which observations were made both at Bassour and at Mount Wilson. On June 6, 1912, a great volcanic eruption occurred at Mount Katmai in Alaska; on June 19 the sky became slightly turbid in Bassour, and a day or two later also at Mount Wilson. The milkiness rapidly increased till in July and August a thick haze overspread the whole sky and cut off more than 20 per cent. of the sun's direct radiation at noonday; yet after applying properly determined corrections, normal and accordant values of the solar constant were obtained at Bassour and Mount Wilson during the above period.

The variability discovered in the sun's radiation is of two kinds; irregular variations occur over periods of a few days or weeks, amounting to a small percentage of the whole intensity, while small variations of longer period are found, showing some correlation with the periodicity of sunspot activity. Considering how marked are the changes in solar-spottedness, and in the accompanying magnetic and auroral phenomena upon the earth, it is remarkable how small are the variations in the main solar radiation. Many attempts have been made to connect the sunspot cycle with meteorological changes likely to depend on the solar radiation reaching the earth, but with very doubtful success—the terrestrial factors which share in determining the weather and crops are too complicated, and it now appears that the long-period changes in the solar radiation are themselves very small. Hence they were bound to remain undetected till direct methods and appropriate instruments were devised which made possible a frontal attack upon the problem. The method which has proved successful is due to S. P. Langley, and the spectro-bolometer which he invented (in 1880) is one of the chief instruments employed; but many improvements and additions both of method and in the instrumental equipment have been since made, and largely by the staff of the Smithsonian observatory under its director Dr. C. G. Abbot.

Langley's method is, briefly, as follows. Absolute measurements of the total solar radiation reaching the earth's surface are made with an instrument (the pyrheliometer) which indicates the heat energy absorbed by a blackened silver disc exposed to the radiation. It is claimed that the error of a single reading with this instrument is less than 1 per cent., and inter-comparison of pyrheliometers over periods of several years shows that the scale is free from secular changes exceeding 1 per cent. Such absolute observations are made at frequent intervals during a forenoon or afternoon, with the sun at different altitudes from 15° upwards; the measurements vary on account of the varying absorption as the radiation passes through a greater or lesser length of atmosphere.

The correction for the absorption is obtained with the aid of the spectro-bolometer, which consists essentially of a wire on which radiation of a particular wave-length is directed, after passing through a suitable prism. The resulting rise of temperature in the wire is measured by the change in its electrical resistance, and by passing the whole available spectrum over the wire a "bolograph" showing the energy-intensity curve over the solar spectrum is obtained. Such bolographs, corresponding to different successive altitudes of the sun, show the absorption in all parts of the spectrum during the passage of radiation through lengths of the atmosphere proportional to the secants of the sun's zenith distance; their comparison makes it possible to correct each bolograph for the absorption. In certain regions of the energy-curve where powerful selective absorption occurs by water and other atmospheric vapours, it is assumed that the absorption bands are absent outside the atmosphere, the curve being completed by interpolation between adjacent parts of the curve on either side.

While highly sensitive, the bolograph gives relative rather than absolute measures of solar radiation, and the scale of the uncorrected bolograph is obtained by comparing its area with the value of the total radiation as measured by the pyrheliometer. The bolograph corrected for absorption then gives the value of the solar constant. It is estimated that the probable error of an ordinary daily determination of the latter is from 0·2 to 0·3 per cent. as regards the relative values from day to day, *i.e.* omitting the probable error of the pyrheliometer scale value. The whole daily error should therefore be well below 1 per cent. under good conditions, though at times irregular or systematic errors of larger magnitude may occur.

The absolute value of the solar constant, determined from 1244 observations, mainly at Mount Wilson

[1] "Annals of the Astrophysical Observatory of the Smithsonian Institution." Volume iv. By C. G. Abbot, F. E. Fowle, and L. B. Aldrich. Pp. xii+390. (Washington, 1922.)

(1912–20), but also at Calama in Chile (1918–20), is given as 1·946. Dr. Abbot admits, however, a criticism by Kron, to the effect that this value may be 2 per cent. too low owing to a systematic influence tending to magnify the measured atmospheric transmissibility for ultra-violet rays. The error does not affect the evidence for variability in the solar radiation.

The above value is slightly greater than the mean (1·933) for the epoch 1902–12, and it is suggested that the increase is associated with the greater average solar activity during the later period. Whether this be so or not (and the more detailed comparison of values of the solar constant with sunspot numbers scarcely strengthens the evidence for such a connexion) the really remarkable result is the minuteness of the change; the solar agent which affects the diurnal variation of terrestrial magnetism must vary by 20 per cent. or more, instead of ½ per cent. or 1 per cent., as here. There is, of course, a very slight compensation for any general increase of solar emissivity at times of many sunspots, owing to the diminution of emitting surface caused by the presence of the low-temperature spots; if there are also absorbing vapours above the spots, the compensation may not be merely slight; an appreciable drop (about 5 per cent.) in the solar constant coincided with the passage of a very large group of sunspots across the sun's disc in March 1920.

The short-period "solar-constant" variation, of amount from 2 to 10 per cent., has been further confirmed by simultaneous observations at Mount Wilson and at Calama, Chile; these stations are about 5000 miles apart, on opposite sides of the equator, and at different altitudes. Their observations show a moderate degree of correlation (0·491). Attempts have been made by Dr. Abbot and his colleagues to find connexions between the variations of the solar constant and the variations of contrast of brightness on the sun's disc which have been revealed by observations of the distribution of radiation over the sun's surface. Such measures have been carried on now for more than eight years by the Smithsonian observatory. The association between the two phenomena, if real, is very complex; high contrast sometimes accompanying high, and sometimes low, values of the solar constant. A correspondingly complex theory is propounded to account for this, but a much longer series of observations is required to test the theory. Dr. Abbot urges the desirability of other observatories taking up solar-constant work, especially in view of the possibility that variations of radiation have predictable meteorological consequences, as Clayton's studies might suggest.

Various other cognate researches have been made by Dr. Abbot and his colleagues, Messrs. Fowle, Aldrich, Moore, and Abbot, during the period, since 1912, dealt with in the volume of Annals before us. Variations in the solar radiation have been tentatively sought by observing the changing brightness of the planets. The sun's total radiation has also been measured, at various terrestrial altitudes, from sea-level to high mountain stations and beyond, up to 25,000 metres by sounding balloons. A new empirical method of determining the solar constant by observations occupying only fifteen minutes in all has been introduced at Calama; this removes one of the chief sources of error in the longer method, namely, real variations in atmospheric transparency during the observations. In the new method the amount and character of the atmospheric absorption at the time of a pyrheliometer observation is inferred from a measure of the brightness of the sky in a zone 15° from the sun, and from the intensity of a particular water absorption band observed by means of the bolograph. Many observations of the brightness and transmissive power of the atmosphere have been made in the course of this and the other parts of the solar-constant work. Laboratory studies have been made on the absorption of long-wave radiation by water vapour, carbon dioxide, ozone, and by many common solid substances. The reflecting power of clouds has been measured by balloon observations at Mount Wilson in 1918; the ratio of reflection found was 78 per cent., independent of the solar altitude. From this the albedo of the earth is estimated at 43 per cent.

On account of over-frequent cloud and haze at Mount Wilson the solar-constant work carried on there since 1915 has been transferred to Mount Harqua Hala in Arizona, and the Calama station in the plain has been removed to Mount Montezuma, a few miles away. For a short time in 1917–18 observations were made at Hump Mountain in North Carolina, but the situation proved too cloudy. It is interesting to note, however, that one excellent observation was made at a lower air temperature than any experienced elsewhere during a complete solar-constant observation; both the hands and feet of the observer with the pyrheliometer were frozen in the course of the measurements!

Obituary.

W. H. WESLEY.

WILLIAM HENRY WESLEY, who died on October 17, at the age of eighty-one years, was appointed assistant secretary of the Royal Astronomical Society in 1875, and continued in that office till his death, a period of forty-seven years. He had excellent qualifications for the post, being most orderly and methodical in all secretarial and editorial work, and having great skill as a draughtsman and engraver, as was exemplified in his engravings of Dr. Boeddicker's drawings of the Milky Way, and the illustrations of the corona in Mr. Ranyard's memoir on solar eclipses. It used to be said that Wesley knew the corona better than any man living, although he had never seen it; however, after an unsuccessful effort in Norway in 1896, the equatorial *coudé* at Algiers was put at his service by M. Trépied in 1900, when he made a detailed drawing in the short duration of totality (64 seconds) and expressed his opinion that the eye was no more efficient than the photographic plate for this work. He made combination drawings from the negatives obtained by the Greenwich staff in the eclipses of 1898,

1900, 1901, 1905, and these will probably be reproduced.

Fellows of the Royal Astronomical Society will long remember Wesley's readiness to help them in their researches, and to put his intimate knowledge of the society's library at their service. He was an original member of the British Astronomical Association, and served as vice-president for many years; on one occasion he delivered the presidential address in place of the late Mr. Green A. C. D. CROMMELIN.

PROF. C. MICHIE SMITH.

CHARLES MICHIE SMITH, who died on September 27, was born on July 13, 1854, at Keig, Aberdeen. He studied at Aberdeen and Edinburgh, graduating as B.Sc. in 1876. He was appointed professor of physics at the Christian College, Madras, in the same year, and in 1891 became Government Astronomer at Madras. In 1899 he brought out the New Madras General Catalogue of 5303 stars the low latitude of Madras gives its star catalogues special importance, since they serve to link the northern and southern catalogues.

Michie Smith observed the annular eclipse of 1894, and the total one of 1898 at Sahdol, obtaining some beautiful large-scale coronal photographs. He also observed the Leonid meteors in 1899, including 37 of the first magnitude (Mon. Not. R.A.S., vol. 60), and published an extensive record of meteors seen at Madras from 1861 to 1890 He also observed the Zodiacal light, and wrote the article on this subject in the "Encyclopædia Britannica" (9th edit.)

Regular meteorological observations were made at Madras, and in 1893, Michie Smith published those of the years 1856 to 1861 He also contributed papers to the Royal Society of Edinburgh on the eruption of Bandaisan, the determination of surface-tension by measurement of ripples, and on atmospheric electricity and the absorption spectra of vegetable colouring matters It was under his initiative that the mountain observatory at Kodaikanal was inaugurated in 1899, which has played such an important part in the extension of our knowledge of solar physics He presided over the two observatories from 1899 till his retirement in 1911, when he was succeeded by Mr. Evershed.

WE regret to announce the death of the eminent scholar and editor, Dr. James Hastings, at the age of seventy-one years. The various Dictionaries of the Bible published under his control have enjoyed much popularity, combining with the orthodox position the results of modern criticism. But his greatest work was the "Encyclopædia of Religion and Ethics," the publication of which began in 1908 and ended with the twelfth volume in 1921. Like all works of the kind, it is uneven, but to the student of comparative religion, ethics and philosophy, anthropology and folklore, it is of the highest value. Hastings was a model editor, quiet and unassuming, sparing no pains to verify a fact or a reference; he maintained the most agreeable relations with his many contributors, some of whom must have tried his patience sorely. His fault, if it be a fault, was excessive kindness and hesitation in using his blue pencil when he was dealing with men who were recognised authorities on the subjects which they undertook. The war, which interfered with his arrangements with foreign scholars, added much to his anxieties, and the work must have come to a temporary end if he had not been generously supported by his publishers He had planned a general index of the Encyclopædia, which will add much to its value for the working scholar It is to be hoped that the scheme for the index was drawn up before his sudden, untimely, and much regretted death.

IN the *Chemiker Zeitung* of September 28 the death is announced on September 15 of Prof. F. Nobbe, of the Forestry Academy of Tharandt, the founder of the research station of plant physiology and the first station for seed control.

WE notice with much regret the announcement of the death on October 26, at sixty-six years of age, of Dr. C. G. Knott, reader in applied mathematics, University of Edinburgh, and on October 28, in his eighty-fifth year, of Prof. A. Crum Brown, emeritus professor of chemistry in the same university.

Current Topics and Events.

MUCH anxiety is felt in this country as to the position and prospects of the Royal College of Science, Dublin, under the Irish Provisional Government By a sudden decree, the college was closed on October 1 —a day before the new session would have opened It was announced that a bomb had been found in the building, and this provided a plausible excuse for the action taken No students had, however, been admitted to the college since June 30, and the circulation of the rumour as to the discovery of the bomb was known to be merely a means of suggesting that the college was a centre of disaffection and that in the interests of public safety it should be closed For a week or two afterwards the teaching was carried on in buildings lent by the National University, but a second decree was made on October 16 ordering the students, about four hundred in number, to enter the National University classes, an arrangement against which both professors and students strongly protested. A compromise may be effected, but meanwhile the Royal College of Science is in the complete occupation of the military, and no one in authority will say that the building will be restored to its original purposes when military necessity ceases. It would be nothing short of a calamity if an institution in which so much valuable scientific work has been carried on for many years should have its activities abruptly ended to serve purely political purposes The college is unique in Ireland; its equipment cost more than 250,000*l.* and no other

institution or university in that country can offer the same facilities for training. It must be heartbreaking to see the practical equipment and apparatus, the fine electric machinery plant, engineering department, and laboratories generally, used for kitchens and bedrooms and at the mercy of military forces unfamiliar with their significance or value. It is almost impossible to get exact information as to the actual position of things in Dublin, but if conditions are half so bad as have been described to us, men of science and scientific institutions should unite to bring them to the notice of their colleagues in other parts of the British Isles and the world of progressive knowledge in general, in the hope that provision for the scientific instruction and research much needed by Ireland will not be curtailed but extended in the near future.

THE Marquess of Crewe has accepted the invitation of the council of the British Science Guild to succeed Lord Montagu of Beaulieu as president of the Guild. Lord Crewe has always taken much interest in the promotion of scientific research, and it was while he was Lord President of the Council in 1915 that the Government scheme for aiding the formation of Industrial Research Associations was announced by him. The British Science Guild is not directly concerned with the methods and results of research in the same way as are the various scientific and technical societies, but with securing adequate facilities not only for extending scientific knowledge itself but also for using it for national progress. Its relation to such societies is similar to that of the Navy League to the navy, and the need of such a body, watching and intervening on behalf of science, and in the interests of administrative efficiency and national development, is as great to-day as ever it was. We understand that the Guild proposes shortly to make a wide appeal for support to extend its activities and to enlighten the general public as to the significance of scientific work and thought in modern civilisation by means of leaflets, lectures, conferences, and so on. The campaign is a promising one, and for the sake of science as well as for national security, we trust it will be markedly successful.

AMONG the scientific men who lived during the Revolutionary Era in France few were held in higher esteem than Claude Louis Berthollet, the centenary of whose death occurs on November 6. Celebrated for his discovery, in 1785, of the composition of ammonia and, in 1786, of the bleaching properties of chlorine, he was one of the earliest converts to the new ideas of Lavoisier, and with Lavoisier, Fourcroy, and Guyton de Morveau, compiled the "Méthode de Nomenclature Chemique." During the Revolution his organising powers were devoted to maintaining a supply of saltpetre for the making of gunpowder, while with Monge and Clouet he did much to improve and extend the manufacture of steel. He also played a prominent part in the reorganisation of the Academies and the inauguration of the National Institute. Like Monge, he was a favourite with Napoleon and was one of the group of learned men who accompanied the young conqueror to Egypt. Among Berthollet's writings was his "Statique Chimique," published in 1803. He was the founder of the famous "Société d'Arceuil," of which Laplace, Biot, and Gay-Lussac were members.

THE secretary of the Swedish Medical Society has favoured us with the following particulars of the Anders Retzius medal which was awarded recently to Sir Charles Sherrington. The Anders Retzius foundation was given to the society on October 13, 1896, by Mrs. Emilie Retzius in memory of the hundredth anniversary of the birth of her late husband, Prof. Anders Retzius, and it is intended to promote studies of normal anatomy and physiology. From this foundation the Anders Retzius gold medal was for the first time awarded by the society to Albert von Kolliker in the year 1897. It has since been awarded successively on every fifth year to Carl Voit, Gustaf Schwalbe, John Newport Langley, and Oscar Hertwig, alternately in recognition of their prominent anatomical and physiological researches. The medal is sixty-nine millimetres in diameter, was designed by the Swedish medallist E. Lindberg, and represents Anders Retzius's portrait in profile.

MR. W. FRENCH, writing from the Storey Institute, Lancaster, directs our attention to a letter from Prof. A. C. Seward, published in the *Lancaster Observer* for September 22, referring to the state of the tombstone marking the grave of the parents of Sir Richard Owen and appealing to Lancastrians to contribute the comparatively small amount required for its restoration. Mr. French suggests that there may be many scientific men yet living who owe much of their success and inspiration to the writings and teachings of Sir Richard Owen, and would be willing to acknowledge in part their debt to him by contributing to the restoration of the tombstone of his parents. The estimated cost of the project is about 30*l.*, and Mr. French is willing to receive subscriptions and to give any further information that is required. We feel sure that readers of NATURE will share the desire of Prof. Seward and Mr. French that anything associated with the memory of so distinguished a man of science should be preserved and treated with the greatest reverence.

IT has been announced in our columns (September 16, p. 394) that nearly 850*l.* had been subscribed in this country in support of the Pasteur centenary celebrations. This sum has been forwarded to the general treasurer of the fund, M. Th. Héring, who, in his reply acknowledging the receipt of the gift, states that any surplus of funds remaining after providing the monument at Strasbourg will pass to the Pasteur Foundation, which will probably institute Pasteur prizes for needy students. In February next, the Alliance Française, of 41 Fitzroy Square, W.1, is entertaining for a few days MM. Vallery-Radot, father and son, relatives of Pasteur, and Dr. Pasteur Vallery-Radot will give an address on the work of his illustrious grandfather. MM. Vallery-Radot will afterwards be entertained at dinner, probably at the Vintners' Hall.

IN the *Daily Mail* of October 23 appears a note on the discovery of a human skull and bones in an ancient gold-working at Gwanda, Rhodesia. It is based upon an account of the discovery by Mr. Duncan Simpson, by whom the bones were found in July last. They lay under twenty feet of débris, and their position would suggest that the miner was working on the face of the reef when he was killed by a fall of the rock. This is supported by the fact that a large stone hammer lay near by, which, it may be assumed, he was using at the time. The bones are now in charge of Dr. Arnold of the Rhodesian Museum and are to be submitted to expert investigation. It is stated that on a cursory examination they are thought to be those of a Bantu. If, as the circumstances suggest, the remains are those of one of the original miners of the ancient gold-workings, in which this part of Rhodesia abounds, they are the first to be discovered. The confirmation of their Bantu origin would have an important bearing upon the problem of the origin of these gold-workings and of the highly developed ancient culture of Rhodesia which has so often been the subject of controversy. While it is highly probable that the workers were the slaves of a higher race, as suggested in the *Daily Mail* article, the Bantu origin of these early miners, in view of the comparatively late incursion of that race into this area, would preclude a very high antiquity for these workings.

A SNAP of cold and severe weather was experienced over the British Isles during the closing days of October, and temperatures were exceptionally low for so early in the winter season. Bitter easterly winds were prevalent under the controlling influence of a region of high barometer centred over Iceland and an area of low barometer readings situated over France and the Bay of Biscay. In the English Channel and on our south coasts the east winds attained the force of a gale. Snow fell in Cornwall and at many places in the southern counties on Saturday, October 28. According to the reports from the Meteorological Office, the thermometer on October 28 and 29 failed to reach 50° F. in any part of the Kingdom, whilst on October 29 the maximum at Falmouth, Newquay, Lympne, and Hampstead was only 39° F. and at night sharp frost was generally experienced, the exposed thermometer falling to 20° F. in many places. The Greenwich temperature records from 1841 show that in six years, 1859, 1869, 1873, 1880, 1890, and 1895, the maximum day temperature in October failed to attain 40°, on a single day, at least, subsequent to October 20. At Eastbourne the highest temperature on Sunday, October 29, was 42° F., and on three mornings, October 26, 27, and 29, the lowest temperature in the shade indicated a frost. October was generally cold and fairly dry in most parts of England, with a large amount of easterly wind, and was in marked contrast to the warm and bright weather experienced in the corresponding month of last year.

THE anniversary dinner of the Royal Society will be held at the Hotel Victoria (Edward VII rooms) on St. Andrew's Day, Thursday, November 30.

THE annual exhibition of scientific apparatus organised by the Physical Society of London and the Optical Society will be held on January 3 and 4 next.

AT the first ordinary meeting of the new session of the Royal Geographical Society, to be held on November 13 at 8.30 P.M., at the Aeolian Hall, a paper will be read by Commander Frank Wild on the work of the *Quest*.

THE Huxley Lecture of Charing Cross Hospital Medical School will be delivered at the school on Wednesday, November 8, at 3 o'clock, by Sir Arthur Keith, who will speak on "Evolutionary Tendencies in Man's Body." At 4 o'clock on the same day, at London Hospital Medical College, Dr. Percy Kidd will deliver the Schorstein Memorial Lecture. The subject will be "Forty Years in the History of Tuberculosis."

AT a meeting of the Royal Society of Edinburgh on October 23, the following officers and members of council were elected:—*President*: Prof. F. O. Bower. *Vice-Presidents*: Sir J. A. Ewing, Prof. J. W. Gregory, Major-General W. B. Bannerman, Dr. W. A. Tait, Principal J. C. Irvine, Lord Salvesen. *General Secretary*: Dr. C. G. Knott. *Secretaries to Ordinary Meetings*: Prof. J. H. Ashworth, Prof. R. A. Sampson. *Treasurer*: Dr. J. Currie. *Curator of Library and Museum*: Dr. A. Crichton Mitchell. *Council*: Prof. F. G. Baily, Dr. R. Campbell, Prof. J. Arthur Thomson, Dr. H. S. Allen, Sir Robert Blyth Greig, Dr. J. Ritchie, Prof. E. M. Wedderburn, Prof. T. H. Bryce, Prof. J. Y. Simpson, Prof. D'Arcy W. Thompson, Sir James Walker, Prof. E. T. Whittaker.

IN her presidential address, delivered on October 19, to the Society for Constructive Birth Control and Racial Progress, Dr. M. C. Stopes dealt with the ideals and present position of constructive birth control. She stated that the social ideal urgently needed to-day is the revision of our present mistaken tendency to breed from defective stock more than from good and healthy stock. Acting as a motive force is also the individual human commiseration for the sufferings endured by unhealthy, over-burdened slum women, involuntarily the mothers of degenerate stock. Dr. Marie Stopes is of opinion that the Utopian idea is attainable through the use of scientific knowledge in such a way as to secure the increase from the best, and to decrease the population of low-grade human beings.

MESSRS. W. HEFFER AND SONS, LTD., booksellers, Cambridge, have recently purchased the interesting and valuable library of Prof. R. B. Clifton, late professor of natural philosophy in the University of Oxford. They have a catalogue in preparation. A copy will be sent post free on application.

WE have received from Mr. W. Rodier, 327 Collins Street, Melbourne, a letter and some pamphlets dealing with the rat problem as bearing upon the article by Mr. Alfred E. Moore in our issue of May 20 (vol. 109, p. 659). Mr. Rodier's scheme for the extermination of rats, known as "The Rodier System," which consists in liberating all the males trapped, is of course well known and its merits thoroughly appreciated by all interested in the destruction of

the rat. Mr. Moore, to whom we submitted Mr. Rodier's communication, sends us the following comments upon it. "Boelter, who joined me soon after I had initiated the British war on rats and mice, agreed with me that if we could get international, unified, and synchronised war on the rat, then and not till then could we hope to have any success from Mr Rodier's method, we agreed that our first step must be to get the public fully to appreciate the disastrous nature of the rat menace, but that we could not afford to postpone rat destruction by all and every means until the day when unified effort was forthcoming If Mr Rodier agrees to work for an International Commission to bring about a proper understanding of the rat problem and concerted action, then I am sure all of us would gladly co-operate; but until we can get the public mind fully alive to the extent of the issue, I am sure it would be just as reasonable during the fly season to catch as many flies as possible and to liberate all the males in this instance at any rate we should have a fair chance of seeing the progress of our work"

Readers of Nature interested in topography may like to have their attention directed to a catalogue of some 230 books, maps, and engravings relating to London and its vicinity just issued by Mr F. Edwards, 83 High Street, Marylebone, W 1

The useful quarterly list of new books and new editions added to Lewis's Medical and Scientific Circulating Library for the months July to September has just been received Copies are obtainable free of charge from Messrs H K Lewis and Co, Ltd, 136 Gower Street, W C 1

Mr W H Robinson, 4 Nelson Street, Newcastle-upon-Tyne, has recently issued a catalogue of some 300 second-hand books of science The prices asked seem very reasonable An interesting item is a copy of the first edition in English of The Anatomical Exercises of Harvey, concerning the Motion of the Heart and Blood, with the Preface of Zechariah Wood, Physician at Roterdam, to which is added Dr James De Back, his Discourse of the Heart, containing a defence of Harvey's work

A Directory for the British Glass Industry is being compiled under the auspices of the Society of Glass Technology It will contain in classified form the names of all firms, associations, societies, trade unions, educational and research institutions interested in the manufacture and wholesale supply of glass and glass articles, and in the supply of raw materials, plant, and machinery to the industry It is hoped to publish the volume by the end of the present year

Our Astronomical Column.

Recent Meteors Mr W F Denning writes that two large meteors were seen at Bristol on October 17 at 7 15 and 10 46 The first of these descended just under the "Pointers" in Ursa Major from 164° + 52° to 161° + 45°, and moved very slowly The other meteor traversed an unusually long path of 113 degrees, the flight being from 163° + 74° to 330° − 6° The duration was about six seconds, and the meteor threw off a bright streak all along its extended course The radiant point was near the horizon in 152° + 39°, but no further accounts of the object have yet been received

The October meteoric shower has been fairly well observed this year, a remarkable succession of clear nights having occurred between October 10 and 21 The chief showers have been from Orion and Aries Mr Prentice at Stowmarket saw 246 meteors between October 10 and 18 in 34 hours of watching The chief radiants in activity were determined by him as follows

α Arietids .	31°	+19°	8 Meteors,	October	13-15
ε Arietids .	41½°	+22°	17 ,,	,,	14-18
ν Orionids .	90°	+16°	10 ,,	,,	18
ζ Geminids .	98°	+15°	8 ,,	,,	14-15

These various showers are well known at this period of the year The Arietids are slow-moving, brilliant meteors, while the Orionids and Geminids are swift, streaking meteors

Occultation of Aldebaran.—On Monday next, November 6, the moon will occult the bright star Aldebaran in Taurus The disappearance takes place at $10^h\ 8^m$ G.M.T., and the reappearance at $11^h\ 20^m$ G.M.T.

Comets.—Numerous observations are to hand of the comet discovered by Dr. Baade on October 19 The comet is easily visible in a moderate telescope, and should be observable for some months. It is, however, receding from the sun and earth The following elements are by Mdlle Vinter Hansen, from Copenhagen observations on October 22, 23 and 24:

$$
\begin{aligned}
T &\quad 1922\ \text{Oct}\ 16\ 5701\ \text{G M T} \\
\omega &\quad 114^\circ\ 32'\ 07 \\
\Omega &= 219^\circ\ 50'\ 89 \\
i &\quad 51^\circ\ 17'\ 00
\end{aligned}
\Bigg\}\ 1922\ 0
$$

$\log q = 0\ 35890$

Ephemeris for Greenwich Midnight

		R A h	m	s	N Decl			log r	log Δ.	Mag.
Nov	6	20	28	4	32°	36′	0			
	10	20	37	13	31	28	1	0 3622	0 3035	10 1
	14	20	47	28	30	21	4			
	18	20	57	18	29	16	2	0 3646	0 3150	10 2
	22	21	7	10	28	13	0			

The comet should be looked for high up in the south-west soon after sunset

The search ephemeris lately given for Perrine's periodic comet did not include perturbations. M Kasakov of Moscow finds that these are large, and gives the following elements.

$$
T = 1922\ \text{Dec}\ 25\ ?
$$

$$
\begin{aligned}
\omega &\quad 167^\circ\ 15'\ 21 \\
\Omega &= 242^\circ\ 18'\ 53 \\
i &\quad 15^\circ\ 42'\ 56
\end{aligned}
\Bigg\}\ 1922\ 0
$$

$$
\phi = 41^\circ\ 15'\ 63
$$

$$
\mu \quad 537''\ 538
$$

Ephemerides for Greenwich Midnight with Two Assumed Dates of Perihelion.

		Perihelion Dec 21 2 R A h	m	s	N Decl		Perihelion Dec. 25 2 R.A. h	m	s.	N Decl.	
Nov	10	21	14	5	5°	29′	20	58	7	3°	9′
	18	21	35	11	4	35	21	17	53	2	33

Dec	4	22	27	1	3	21	22	5	53	1	58

It is some 26′ south of the other comet, but considerably fainter.

Research Items.

A LONG BARROW IN BRECONSHIRE.—In the October issue of *Man*, Mr. C. E. Vulliamy describes the results of his excavations of a long barrow at Talgarth in Breconshire, on a foothill of the Black Mountain range. The chamber and its contents had been disturbed, but not in recent times. At an early stage a calcined thigh-bone of a youth was found, but lower down there were abundant human remains, much broken and seldom lying in anatomical relation to each other, but showing no evidence of cremation. Sir Arthur Keith, who has examined the fragments, finds one skull of a man about forty years of age, the cephalic index 70, a very narrow, relatively high, and rather small head, 20 mm. narrower than previously recorded in Neolithic skulls from Wales. Associated with the human remains were bones of the pig, ox, goat, and cat, and quantities of flint flakes and scrapers are scattered over the neighbourhood.

A THIRD-CENTURY BIRMINGHAM.—Preliminary excavations have just been completed on the site of what the *Times* calls "a third-century Birmingham," Ariconium, in the Wye valley between Monmouth and Gloucester, near Weston-under-Penyard, three miles from Ross. Over an area of more than 100 acres the earth is full of smelting refuse; evidently a great iron industry flourished there, the iron ore being brought from the Forest of Dean. The only classical reference to the place is in the Itinerary of Antoninus, compiled about 150 A.D., and in the fourteenth century the Benedictine monk Richard of Cirencester refers to it. Some buildings have been found, the walls of which were decorated in colour. A large quantity of pottery, fragments of Samian ware, and a coin of Domitian dated 87 A.D. were also discovered. Ariconium seems to have arisen as a halting-place on the Roman road from Caerleon to Silchester in the first century, and it became a busy industrial town in the third. The results of these excavations justify their continuance on a wider scale.

BACTERIOLOGY OF CANNED MEAT AND FISH.—The results of an investigation by Dr. W. G. Savage and Messrs. R. F. Hanwicke and R. B. Calder on the bacteriology of canned meat and fish have been published by the Food Investigation Board as Special Rep. No. 11 (H.M.S.O. price *2s. 6d.* net). The report is based on the examination of 344 samples, the object being to ascertain the character of bacteria concerned in the spoilage of these canned foods. Moulds and yeasts are of rare occurrence and probably of little importance. Obligate anaerobic bacilli are rarely present in sound tins, but were nearly always associated with obtrusively decomposed conditions in the tin. Sporing aerobic bacilli are frequent in sound samples, and many of them must be regarded as potential causes of decomposition, they are unable to develop in sound tins from which air is excluded and persist as harmless spores. Non-sporing bacilli were found in many samples, their importance depending upon their biological characters. Thus, strains of *B. proteus* are important causes of decomposition. Thermophilic bacteria (*i.e.* bacteria growing best at 55° C.) were searched for and found to be widely prevalent but, being non-proteolytic, are unlikely to cause spoilage. Micrococci are infrequent and as a group cannot be regarded as a cause of spoilage, though they may assist more proteolytic types of organisms. Nearly 62 per cent. of sound tins are not sterile, the worst offenders being crab and lobster. Sterility itself is therefore not a criterion of soundness, and these surviving bacteria do not in any way injure the foods in which they are present owing to their inability to multiply and produce decomposition under the conditions existing. Suggestions are made respecting the process of manufacture so as to reduce spoilage to a minimum.

FLOWER STRUCTURE IN THE LECYTHIDACEÆ.—Prof. McLean Thompson has published a further study of floral morphology in the Lecythidaceæ, a peculiar tropical family with large fruits, related to the Myrtaceæ (Trans. Roy. Soc. Edin., Vol. 53, Part I., No. 13). The present paper is devoted to a study of the flowering and certain stages in the floral development of *Napoleona imperialis*, the first member of the West African genus Napoleona to be described, in 1786, by a French writer. The peculiarities of the flower include so-called inner and outer corollas with a series of petaloid filaments between them. Many interpretations have been placed upon these structures. The floral development indicates that the petaloid filaments and the outer corona have taken the place of the outer cycles of stamens in the Myrtaceous flower, as Bentham supposed. The style is surrounded by a fleshy glandular disc which is considered to be a remnant of an inner stamen-bearing whorl.

HAWAIIAN GRASSES.—A comprehensive account of the grasses of the Hawaii islands, which is based on special collections made by the author in 1906, and on all accessible material gathered by other observers, is provided in Memoirs of the Bernice Pauahi Bishop Museum, Vol. VIII., No. 3 (Honolulu), "The Grasses of Hawaii," by A. S. Hitchcock. The preliminary discussion deals with the distribution from an ecological standpoint, with the chief agricultural grasses, and with introduced species. A large number of the grasses of the islands have been introduced, 83 species in all, mostly from Europe, a few from Australia and the East Indies. Many of the 47 native species are endemic, and most of the others have extended northwards to Hawaii from the East Indies and the southern Polynesian islands. Of the 39 endemic species 7 are annuals, all belonging to the genus Panicum. The second part is systematic and gives a full description of each species, the necessary keys being provided; 9 new species are described, together with a new section of Poa, Siphonocoleus sect. nov. The treatise should provide a useful and well-arranged reference work for students of the Gramineæ.

WEST INDIAN HURRICANES.—An article on the formation and movement of West Indian hurricanes by Mr. E. H. Bowie of the U.S. Weather Bureau appears in the U.S. *Monthly Weather Review*, April 1922. The area of first appearance is described as extending from latitude 10° to 25° N. and from longitude 56° to 95° W. During a period of 35 years, 90 per cent. of the West Indian hurricanes are said to have had their origin within and not without this area. It is asserted that some years pass without hurricane formation, while other years are notable for hurricane frequency. The origin of a hurricane is by no means certain, and the author states it is even now difficult and next to impossible to say which of the many hypotheses is the correct one. The prevalent supposition of the origin is the meeting of adverse currents, having different temperatures, which produce gyratory motions of the atmosphere. Many men of science are of opinion

that tropical cyclones are essentially convectional phenomena. Observations in the free air in and around a tropical cyclone are not available. Dr. V. Bjerknes, in his theory of the polar front, has recently given a new conception of the part that local wind systems play in the formation of cyclones. The author states that it would seem that the cause of the origin of the tropical cyclone may be found in the counter current theory as to initiation of the cyclone centre, while the convective theory accounts for its maintenance after having started. Much information is given on the movement of hurricanes, and there are numerous charts showing the travelling centres in association with the surrounding distribution of atmospheric pressure.

LOCAL OR HEAT THUNDERSTORMS.—The U.S. *Monthly Weather Review* for June gives an interesting and instructive account of the development of thunderstorms by Prof. C. F. Brooks, of the Clark University, which was presented before the American Meteorological Society in April last. The supply and action of the ascending and descending currents of air are explained, as well as the formation and effect of rain in the development of the storm. The physical make-up of the thunderstorm is said to develop quickly into a central descending and outflaring current of cold air, surrounded by a cone of rising warm air, and still farther out by a zone of descending air. A thunderstorm is described as the result of relatively large streams of air in violent convection attended by abundant condensation of moisture. With reference to the rapid rising of air in cumulus clouds that are growing into cumulo-nimbus, the author remarks that on different occasions his rough measurements have shown upward motions of 3, 4, and 7 metres per second in the tops of cumulus clouds. Aviators and aeronauts who have been within active portions of cumulo-nimbus clouds have experienced great bumpiness owing to the strong up-and-down currents. Violent convection is said to be caused by the instability accompanying a large lapse rate in temperature. Abundant condensation of moisture is essential to the start of a thunderstorm. The gist of the communication is the predicting of local thunderstorms, and certain questions are formulated for the forecaster relative to streams of air, convection, and condensation. It is suggested that the conditions be tabulated and that use be made of a + or − answer, the summing up of which will indicate whether local thunderstorms are probable. Important information is given as to where local thunderstorms originate.

THE SPHERE-GAP VOLTMETER.—When it is necessary to measure the maximum or peak voltage of an alternating current from a transformer or induction coil the sphere-gap voltmeter is often used, as its indications are independent of the humidity of the air and of the form of the voltage wave. The following particulars of such an instrument at the National Physical Laboratory, furnished by Dr. F. A. Owen in the October issue of the *Journal of the Röntgen Society*, will prove useful. The spheres, 7·62 cm. in diameter, are mounted on ebonite pillars 21 cm. long, with sulphur rings 5 cm. long let into them for additional insulation. One sphere is fixed and the other supported on a slide which can be moved towards the fixed sphere by means of a screw. A scale on the slide gives the distance apart of the spheres at their nearest points. The spheres are connected to the supply and are moved slowly towards each other till a spark passes. The peak voltage is then deduced from the distance apart by the following data: 1 cm. 32·7 kilovolts; 2, 60; 3, 86; 4, 196; 5, 124; 6 cm. 141 kilovolts.

OZONE.—Prof. E. H. Riesenfeld, of Berlin, has recently described (*Chemiker Zeitung*, October 7) the preparation and properties of pure ozone. Ozonised oxygen containing 10-15 per cent. of ozone was liquefied in exhausted glass bulbs by cooling in liquid air. The deep blue liquid, on exposure to reduced pressure, gave off mainly oxygen, and at a certain composition separated into two layers: the upper, dark blue, layer was a solution of ozone in liquid oxygen; the lower, deep violet-black, layer was a solution of oxygen in liquid ozone. The lower layer, formerly considered to be pure ozone, contains about 30 per cent. of oxygen at −183° C. The oxygen was pumped off from it, and pure liquid ozone (B.P. −112·4° C.) obtained. The vapour density of 48 (O_3) was found by Dumas' method. On cooling in liquid hydrogen, solid ozone, in violet-black crystals, M.P. −249·7° C. was formed. The gas, deep blue in colour, is, in the absence of all catalysts, remarkably stable. Pure gaseous ozone can be exploded by an electric spark, but some remains unchanged. This would be expected from the endothermic character of the substance. The critical temperature is −5° C. No evidence whatever of the existence of higher polymers of oxygen was obtained: both in the liquid and gaseous states the formula is O_3. This work is of great interest, and, apart from the determination of the physical properties of ozone, it removes the last doubt as to the simple character of ozone—"oxozon" does not exist.

DIFFERENTIAL GAS ANALYSIS.—Mention has already been made in NATURE of a method devised by Dr. G. A. Shakespear of Birmingham University for measuring differences in composition of similar gas mixtures. The method, which has proved itself valuable for controlling the purity of hydrogen, the safety of atmospheres in balloon sheds, and many other purposes, depends on the differences of thermal conductivity of gases. Two identical spirals of platinum wire are enclosed in separate cells in a metal block, each spiral forming one arm of a Wheatstone Bridge circuit, the other two arms being of manganin. An electric current flowing through the bridge thereby heats the two spirals, which lose heat to the walls of the cells. If the two cells contain gases of different thermal conductivities the spirals will cool at different rates, and one spiral will therefore be maintained at a higher temperature than the other. The difference in temperature of the two wires thus causes a deflection of the galvanometer, the extent of which depends on the difference in conductivity of the two gases. The construction is such that changes in the temperature of the gases affect both sides of the bridge equally. If, therefore, one cell contains a pure gas, and the other cell the same gas mixed with some other constituent, the extent of the deflection will indicate the proportion of the second gas present, and the galvanometer can be calibrated to show directly the percentage composition of the mixture. The difference in conductivity between air and carbon dioxide enables the method to be used to determine the percentage of carbon dioxide in flue-gases. The other constituents of flue-gases either have thermal conductivities differing but little from those of nitrogen, or are negligible in amount, while the effect of the water vapour can be counteracted by keeping the gases in both cells saturated. By attention to certain details the method may be then applied to follow the change in carbon dioxide content of the flue-gases in fuel-consuming installations. The instrument is made by the Cambridge Scientific Instrument Company.

The Origin of Magnetism.

WHEN the proposal was first made to hold in Section A of the British Association at Hull this year a discussion on "The Origin of Magnetism," it was met with the criticism from eminent quarters that the time was not yet ripe for the consideration of this subject. Those who attended the meeting will probably agree that this view was justified, for it can scarcely be said that the position was advanced appreciably, or that any real, or even plausible, answer was given to the main question involved. Perhaps this was in some measure due to the regrettable absence of Prof. Langevin, who had promised to make the opening remarks, and had expressed his intention of using the opportunity for a critical survey of the whole subject. But a recurrence of the ill-health from which he has intermittently suffered for a long time deprived the Section of Prof. Langevin's presence and his eagerly anticipated contribution to the discussion. As it was, the discussion lacked co-ordination; the remarks of the various speakers bore little relation to one another. There was the exposition by Prof. Weiss of his theory of the molecular field and the existence of magnetons; then Sir J. A. Ewing's description of his new molecular magnet models; then the remarks of Dr. A. E. Oxley on the changes of susceptibility imparted to platinum and palladium by the occlusion of hydrogen; and, finally, an account by Mr. L. F. Bates of the measurements of the Richardson effect recently carried out by Dr. Chattock and himself,—all contributions of considerable individual interest, but not closely related to one another nor providing an answer to the essential question of the *origin* of magnetism.

In spite of the comparative failure of the discussion in its wider aspects, one felt that the time had not been wasted, principally because it afforded an opportunity for Prof. Weiss to give a most interesting account of his work in connexion with ferromagnetism and paramagnetism, which is not too well known in this country. Prof. Weiss at very short notice undertook to open the discussion in place of Prof. Langevin, and a fairly complete account of his remarks will eventually appear in the Report of the Association. An outline of this exposition may be profitable here.

Starting from the analogy of the difference between the laws of fluid compressibility for low and high densities, Prof. Weiss showed how Langevin's kinetic theory of paramagnetic substances may be modified so as to include strong magnetism—or ferromagnetism—by the assumption of the existence of a *molecular field* analogous to van der Waal's internal pressure in fluids. A whole array of experimental facts was brought forward in support of this theory of the molecular field. It provides an explanation of the variation of magnetic saturation with temperature; it accounts precisely for the transformation of ferromagnetism to paramagnetism at the temperature of the Curie point, and for the observed law of this paramagnetism. The theory also points to a discontinuity of specific heat at the Curie point, and the magnitude of the discontinuity, calculated from magnetic data, agrees with calorimetric measurements. Still more interesting is the recently discovered magneto-caloric phenomenon, which consists of a reversible temperature variation accompanying magnetisation. This differs from the ordinary hysteresis effect, which is irreversible, and always involves heating. In the reversible effect, magnetisation produces a rise of temperature and demagnetisation a fall. At the Curie point the change is by no means negligible, reaching, as it does, a value of about 1° in fields readily attainable. The extent of temperature variation calculated by means of the molecular field theory agrees with that observed.

When one comes to calculate from various experimental data the numerical value of the molecular field, it proves to be of the order of magnitude 10^7 gauss, which is far in excess of the magnetic field which might in the most favourable circumstances be produced by the magnetic moments of the molecules of a ferromagnetic body, namely, 10^4 gauss. This remarkable result indicates that the so-called molecular field has not itself a magnetic origin. In this connexion Prof. Weiss's own (translated) words are worth quoting:—

"It is therefore impossible for the mutual actions represented by the molecular field to be of a magnetic nature. It is just a notation for forces of a non-magnetic character, with a symbol borrowed from magnetism. I prefer, in place of the primitive definition given earlier, the equivalent definition

$$H_m = -\frac{\delta U}{\delta I},$$

where U is the intrinsic energy per unit volume, and I the intensity of magnetisation. This definition is advantageous in that it does not prejudge the nature of the forces. . . It does not appear to be impossible that the forces may be electrostatic; that, however, is at present a pure supposition."

In the second part of his address Prof. Weiss directed attention to another important aspect of the combined kinetic theory of Langevin and his own theory of the molecular field. The possession of these theories permits the calculation of the values of the molecular or atomic magnetic moments which have been the underlying assumption in all theories of magnetism. A great number of atomic moments have thus been evaluated from many experimental sources, such as the measurement of the magnetisation of ferromagnetic substances and their alloys both in the neighbourhood of absolute zero and above the Curie point, the investigation of the paramagnetism of solutions of salts, and the like. The general law which emerges is that "all atomic moments are integral multiples of the same elementary moment, to which the name *magneton* has been given." For example, six different and independent observers have found for nickel, over a temperature interval of about 400°, 8·03, 7·99, 8·04, 8·05, 8·03 and 7·98 magnetons respectively, numbers which, it will be seen, are in the immediate neighbourhood of the integer 8. It is, besides, a general property of atoms to possess different integral numbers of magnetons according to various conditions, such as their state of chemical combination, or their temperature, whether in the ion, or in the undissociated molecule. Prof. Weiss affirms that the magneton is a real entity, and he pointed to the fact that the Rutherford-Bohr atom, together with Planck's quantum theory, actually does indicate the existence of a universal elementary magnetic moment, which, however, proves upon calculation to be almost exactly five times as great as the magneton.

Prof. Weiss's general conclusions may be summed up by quoting him again:—

"1. One of the essential conditions for the production of strong magnetism—or ferromagnetism—is the existence, between molecules possessing magnetic moments, of important mutual actions which are numerically expressed by the molecular field, and are certainly of a non-magnetic nature.

"2 The appearance of atomic moments as integral multiples of the same elementary moment—the magneton—is thus one of the important aspects of magnetic phenomena."

Altogether a convincing exposition, in spite of Sir Ernest Rutherford's amusing allusion to the fascination which *whole numbers* have for physicists.

A. O. RANKINE

Man and the Ice Age.

OF the many discussions which took place during the recent meeting of the British Association at Hull, few are likely, on purely scientific grounds, to prove of more importance than that on the relation of man to the ice age in Britain, in which the sections of geology, geography, and anthropology took part. It cannot be said that any agreement was reached; but the significance of the discussion lies in the fact that protagonists of different schools of thought in geology were brought face to face, while archæologists and geographers were able to formulate and lay before them problems for the solution of which they await the assistance of geologists. In considering the problems of the ice age, geologists and archæologists are dealing with the same material, but each from their special point of view. The result has been a difference in nomenclature and method of classification: the geologist thinks in terms of the deposits; the archæologist in terms of the artefacts found in them. Consequently, as Prof. P. F. Kendall pointed out, any discussion between them is likely to come to a deadlock through disparity of nomenclature. This discussion, however, showed that the difficulty is by no means insuperable.

It was apparent at an early stage in the discussion that there existed a clear-cut difference of opinion as to the method of approach in attacking the problem. Indeed the title of the discussion, in suggesting a restriction of the subject matter to Britain, was a challenge which Prof. W. J. Sollas was not slow to take up, when at the outset he maintained that it was impossible to consider the evidence in Britain apart from conditions on the Continent. Prof. Kendall, on the other hand, held that not merely must consideration be confined to the evidence as it is presented in the British area alone, but that the solution of the problem must be sought in East Anglia in the relation of the northern drift to the chalky boulder clay. On this point, Prof. Kendall's lucid summary of the evidence gave his audience a clear indication of the nature of the problem and of the extent to which the British data may be expected to throw light upon the problem as a whole. It turns to a great extent upon the view which is taken of the relation of the glacial deposits of Yorkshire to those of East Anglia. The chalky boulder clay of East Anglia was carried down by ice from north of the Wash and the fens. In Yorkshire there is a clear glacial sequence of at least three boulder clays, in the lowest of which is a Scandinavian element. In Prof. Kendall's opinion the hope of correlating the Yorkshire evidence with that of East Anglia is to be found in the Wolds, on the west of which is found the purple clay of Yorkshire, and on the east, the chalky boulder clay. Was it possible, he asked, that the latter might be the purple clay transformed by its passage over the Wolds?

The trend of the discussion was to show that the archæological problem is narrowing down to the question of the relation of the gravels containing Chellean and Acheulean implements to the boulder clay, a definite issue for solution by excavation. At Hoxne, such implementiferous gravels were found to overlie a boulder clay, but the evidence is by no means entirely conclusive and appears to conflict with that from elsewhere. Prof. Boswell had hoped to be in a position to place before the sections the results of excavations undertaken to determine this point, but, unfortunately, they had not been completed in time. On the other hand, Mr. Hazzledine Warren showed himself an uncompromising opponent of anything but a post-glacial date for the palæolithic gravels, on the ground that they are conformable to the holocene alluvium, a condition which would be impossible had they been subjected to glacial action. The general disposition appeared to be, however, that further evidence on this clear crucial point must be awaited. On the whole, this would appear to be in agreement with the tendency of the opinions which have been elicited by the British Association Committee appointed at the Cardiff meeting to report on the relation of early types of palæolithic implements and glacial deposits. Of these some have appeared in *Man*, others await publication.

The interest of archæologists and geographers, however, is not bounded by the position of man in relation to glacial deposits in this country. They would wish to know how far conditions in this country can be equated with conditions in the Continental area, extending this term to include North Africa, and how far it is possible by geological evidence to link up the palæolithic cultures of this country with the cultures of these areas. They welcomed, therefore, the opening remarks of the president of the anthropological section, Mr. Peake, in which he referred to the tentative scheme for effecting this which he had put forward,[1] and the pronouncement of Prof. Sollas that the British evidence could not be considered apart from the Continental evidence. Prof. Sollas ably summarised Penck's views, and pointed out how the differences between the French and German geologists might be reconciled—differences however, which did not affect the question of the geological age of man. Penck's four great periods of glaciation in the Eastern Alps could be correlated with the river gravels, while in France glaciation could be brought into relation with raised beaches. As a result of such a correlation, it appeared that the Chellean implements belonged to a warm period, the Riss-Würm, the Mousterian straddled the Würm, and the Aurignacian and later phases of palæolithic culture were post-Würm.

The point of view of the archæologist and geographer was well put by Prof. H. J. Fleure. The archæologist in particular has arrived at certain conclusions on purely archæological evidence, for which he looks to the geologist for confirmation or the reverse. Prof. Fleure pointed out that the three centres of glaciation, Scandinavia, Britain, and the Alps, could not be considered apart. Any change in the distribution of ice in one area was bound to affect the climate and distribution of ice in the others. It was therefore incumbent upon the geologists to produce a scheme applicable to all areas.

An interesting question to which Prof. Fleure alluded is raised in the relation of the Buhl period, which was marked by a readvance of the ice, to the conditions in Scandinavia described by de Geer. The study of climatic conditions may also be expected to throw light upon the problem. Prof. Fleure pointed out that a constant anticyclone over the

[1] *Man*, 1922, No. 5.

glaciated region would cause a constant succession of cyclones accompanied by a high rainfall over the Mediterranean and Western Asia. This would support the view that the desert belt of the Sahara was then more to the south, thus accounting for the vast number of palæolithic implements, accompanied by ostrich shells, found in that area. It would also strengthen the probability that man drifted north as the climate improved after the Wurm period, and confirm the suggestion of the archæological evidence that after the Aurignacian period there is no break

A series of recent investigations on the south coast in Hampshire and Sussex, which were described by Dr. L. S. Palmer, bear very directly upon the question of the equation with Continental deposits. Dr. Palmer, who worked in collaboration with a geologist, had endeavoured to relate climate and deposits with implements As a result, the 100 ft. terraces and beaches show a warm fauna associated with Acheulean and early Mousterian implements; the 50 ft. and 15 ft. terraces a cold fauna associated with Mousterian implements, the cold period being interrupted by a slightly warmer period which justified the division of this phase into two parts. In the superficial brick earths were the Aurignacian, and over the latest Combe rock were the Magdalenian implements. Dr. Palmer found a correspondence between climate, culture, and land oscillations. The investigations were carried out without reference to nomenclature, but on comparison, corresponded with the Continental system of Penck.

At this point the discussion closed If it had attained no very definite conclusion, the air had been cleared. One definite question has been formulated for further investigation, and it has been shown that a considerable body of opinion is approaching some kind of an agreement as to the manner in which the evidence in Britain may be brought into relation with that of the Continent.

Generation and Utilisation of Cold.

THE general discussion on the generation and utilisation of cold which was held at the Institution of Electrical Engineers on October 16 was organised jointly by the Faraday Society and the British Cold Storage and Ice Association.

FIG. 1.—Apparatus used in attempt to solidify helium
C, helium cryostat, M, McLeod gauge, W, resistance manometers, D1, connexion to glass Langmuir pumps, D2, connexion to iron Langmuir pumps

Although the papers read at the meeting dealt with various aspects of the liquefaction of gases, there were no contributions from the refrigerating industry Possibly the applications of cold for the preservation of food stuffs have become so standardised that our refrigerating engineers do not interest themselves in new developments. It was intended that the opening paper of the discussion should be read by Prof. H. Kamerlingh Onnes, but owing to the death of his colleague, Prof. Kuenen, he was unable to be present Consequently Dr. C. A. Crommelin communicated Prof Onnes's paper as well as his own.

The Leyden cryogenic laboratory has been engaged on low-temperature investigations for the past thirty-five years, and such magnificent work has been done there that any communication emanating from this specialised institution is read with considerable interest

Dr. Crommelin's paper was of the nature of a general description of the methods of experiment whereby they obtained any desired temperature below zero centigrade and maintained this temperature constant within 0·01° C The equipment of the cryogenic laboratory is essentially a series of plants working on regenerative Pictet cycles down to liquid nitrogen temperatures Below this, liquid hydrogen and liquid helium are employed. In the Pictet cycles methyl chloride, nitrous oxide, ethylene, methane, oxygen, and nitrogen are used. Any one of the substances boiling under appropriate pressure will give a range of steady temperatures. By these means a range from −24° C. to −270° C is obtained which is complete but for short gaps

Cryostats containing the different liquids are thermally insulated by vacuum walled vessels and the losses reduced to a minimum by the immersion of the apparatus in baths of the commoner elements such as liquid oxygen

For the range −259° to −269° C., which cannot be obtained by the use of a boiling liquid, a hydrogen vapour cryostat is employed, the vapour being heated electrically to the desired temperature and circulated around the experimental bulb.

The paper also contains some interesting data as to the capacity of the plant, and it is stated that liquid hydrogen can be produced at the rate of more than 13 litres per hour. A high degree of purity is required in the gases employed, and it appears that

the ordinary liquid air process of producing oxygen does not give gas of sufficient purity.

Prof. Onnes's paper contains an account of his attempts at producing solid helium and, of course, the attainment of the lowest temperature. His original experiments with helium date back to fifteen years ago, when he found that liquid helium boiling under the lowest pressure he could produce (about 2·2 mm.) did not solidify. The temperature was estimated as 1·15° absolute. In 1920, Onnes determined to make a fresh attempt, using the best pumps available for reducing the pressure. Batteries of Langmuir condensation pumps were constructed, twelve of glass and six of iron, all working in parallel and delivering into two Burckhardt vacuum pumps connected in series with a Siemens oil pump. The largest Burckhardt pump was capable of dealing with 360 cubic metres of gas per hour. A diagram of the experimental arrangements is shown in Fig. 1.

The complete battery of pumps was capable of removing one litre (N.T.P.) of gas per hour under a suction pressure of 0·005 mm., but owing to the gas friction in the apparatus, the actual pressure produced at the surface of the helium was only 0·012 to 0·014 mm. Under these conditions the lowest temperature attained was 0·82° absolute. Even then helium did not solidify.

Not the least difficult part of these investigations is the measurement of temperature. The actual temperature of the liquid is obtained by calculations based upon the general equation of Van der Waal and extrapolating the temperature vapour pressure relationship for helium. The form of the extrapolated curve was compared with those obtained for various other elements as the line shows a decided curvature at normal temperatures. At the meeting Prof. Porter discussed the theoretical basis of this method of extrapolation and the possible error.

The two papers from the Leyden laboratory should prove of material assistance to the student interested in the technique of low-temperature investigations.

The industrial application of the liquefaction processes was dealt with by three speakers. Mr. K. S. Murray gave a general account of the processes employed by the British Oxygen Co. It was interesting to hear that the efficiency of the liquefaction process is not appreciably greater than that of the old barium oxide process using the reversible pressure reaction. The advantage of the liquefaction process is that it produces a purer gas. Figures for the cost of producing oxygen were given, as well as technical descriptions of the various types of rectification apparatus.

The second paper was sent by M. Claude, and in it was described a plant for the separation of hydrogen from water gas by a liquefaction process. The method can be utilised when the gas, such as that from coke ovens, is too impure to permit of the use of the catalytic reaction depending upon the conversion of carbon monoxide to carbon dioxide. The plant described is used for supplying hydrogen to a synthetic ammonia apparatus producing 5 tons of ammonia per day. An interesting feature of the apparatus is the introduction of small amounts of nitrogen into the system to serve as liquid nitrogen lubricant in the expansion engine.

In the third paper, Mr. E. A. Griffiths gave an account of the use of oxygen in breathing apparatus for airmen, and also of the plants for manufacturing liquid oxygen for this purpose. The chief difficulty in the use of cold liquefied oxygen is that of storage and transport. The mechanism of the metal vacuum vessel, which is the only practicable solution of the problem, was briefly dealt with. The manufacture of these vessels is a simple matter, and the thermal losses in properly constructed vessels is 12 per cent. of the liquid oxygen content per day for a flask of two litres capacity, while for a twenty-five-litre flask it is only 4½ per cent.

The vaporisers for converting the liquid oxygen into gas at a rate which can be kept under control were described. In view of the simplicity of these devices, it is surprising that greater use is not made of liquid oxygen in medical and experimental work.

The portable plants employed for producing oxygen utilise both the Claude and the Linde principles. Although the theoretical efficiency of expansion with external work is about three times that possible with the Joule-Thomson free expansion, the actual results obtained on test are not appreciably different. This appears to be due to the practical limitations of the expansion engine. A similar conclusion was arrived at independently by Mr. Murray in the case of large plants.

The expenditure of power for the production of oxygen is of the order of 2½ to 3 H.P. per litre/hour; the figure for the Pictet cycle, according to Crommelin, is decidedly lower, being only 1·64 H.P. per litre/hour. The over-all efficiency of liquefaction processes is therefore extremely low and generally less than 3 per cent.

The remaining papers were contributed by investigators working under the direction of the Engineering Committee of the Food Investigation Board (Department of Scientific and Industrial Research).

Dr. Ezer Griffiths dealt with the determination of thermometric lag in various types of thermometers and with some new materials for thermal insulation at low temperatures.

Prof. C. F. Jenkins gave a summary of his work on the thermal properties of ethyl chloride. His research on this substance is an extension of his previous work on carbon dioxide. The data which he has now obtained should be of considerable value to the refrigerating engineer, for ethyl chloride has many advantages over ammonia and carbon dioxide for use in small refrigerating plants.

E. A. GRIFFITHS.

Propagation of the Sound of Explosions.

IT has frequently been noted that on the occasion of great explosions there are curious anomalies in the propagation of the sound. Usually there is a normal zone of audibility in the immediate neighbourhood of the explosion, beyond this a zone of silence, where the sound is not heard, and again outside the zone of silence a second zone of audibility. It is remarkable that while an observer at say 50 miles away may not hear an explosion, an observer at 80 miles may hear it distinctly.

These abnormalities are closely connected with the meteorological conditions, though the detailed relationship between them is not known. One theory is that the wind lifts the sound over an area and brings it down again many miles away. Another theory ascribes the zone of silence to the effect of the distribution of wind and temperature at high altitudes. The theoretical development of the problem is extremely complex, and so it was decided to make an experimental study of the meteorological conditions along with detailed observations of the extent of the zone of silence in the hope of elucidating the relationship between them.

The International Commission for the Investigation

of the Upper Air appointed a sub-commission to consider the problem set out above, and the sub-commission applied to various Ministries of War with the view of obtaining their collaboration in the case of obligatory destruction of explosives. The first favourable reply came from the Dutch Ministry of War, and it was finally arranged that at 17h G.M.T. on October 28, five tons of ammonium perchlorate should be exploded on the Oldebroek Artillery Drill Ground (longitude 5° 59′ 10″, latitude 52° 29′ 56″).

In this country arrangements were made by the Meteorological Office for the observers at all the observatories and reporting stations to listen for the sound, and to make notes regarding the meteorological conditions at the time. Where possible, observations of wind and temperature in the upper air were also made. In addition, through the medium of the Press, the public were also invited to forward to the Meteorological Office notes of any observations made.

Up to the time of going to press a total of more than one hundred reports have been received and it has not yet been possible to examine them in detail. The most distant points at which the explosion is alleged to have been heard are North Wales and Northumberland. Two valuable records have been obtained on the hot wire microphones of the Signals Experimental Establishment, at Woolwich, and at Biggin Hill (Kent) respectively.

As soon as the British observations have been examined and summarised, the results will be forwarded to the Dutch Meteorological Service for collation with continental reports.

The Whitworth Scholarships.

SEVERAL important changes are indicated in the new regulations for Whitworth Scholarships which have been issued by the Board of Education. In 1923 six Whitworth Scholarships, each of an annual value of 125*l.* and tenable for three years, will be offered for competition, as well as two Whitworth Senior Scholarships of an annual value of 250*l.*, tenable for two years. There are also Whitworth prizes which will be awarded to unsuccessful competitors for the scholarships, not exceeding 25 in number and of value 10*l.* each. The Whitworth Exhibitions (50*l.* tenable for one year) have been abandoned. The scholarships will be open to candidates whose age does not exceed 21 years, and the number of subjects in which candidates will be examined is limited to four. Candidates for the senior scholarships must be less than 26 years of age and will be examined in seven subjects.

The Board has also issued a circular directing attention to the changes, some of which were made last year, in order to render the requirements regarding candidates' practical experience in handicraft more consistent with the present arrangements for apprenticeship and training in mechanical engineering. The Board's experience shows that candidates may be divided into two groups, a large one consisting of candidates whose education since leaving school has been part-time, and for whom a full-time course of study is likely to be suitable, and a smaller one consisting of those who have already completed a full-time course and can take a further course of work of post-graduate standard. Hence the institution of scholarships and senior scholarships.

There still remain difficulties which the new regulations will not remove. In the four years between 17 and 21 years of age a hard-working evening student can reach the ordinary university degree standard in the subjects laid down for the scholarship examinations, but has only touched lightly certain subjects which form part of any organised full-time course. If a scholarship is awarded to him, and he proceeds to a full-time course, he will find that he cannot be exempted from repeating a great deal with which he is perfectly familiar. This difficulty is a very real one, as is well known to every teacher who has been consulted by a successful Whitworth candidate regarding his choice of a suitable college. There is also the difficulty of finding a suitable opening in the works after having been away for three years between the ages of 21 and 24, a difficulty which has led to many promising young men abandoning practical life in favour of teaching.

The circulars issued by the Board convey the impression that they do not favour the plan followed by many of the former scholars, who spent their scholarship term in works offering special facilities for widening their practical experience, and at the same time continued their studies in part-time courses. There is a great deal to be said in favour of this plan, and a glance at the names of former scholars who followed it and have risen to eminence in engineering would appear to justify its reconsideration.

University and Educational Intelligence.

BRISTOL.—The Bristol Medico-Chirurgical Society has offered the society's library as a gift to the University. The library comprises about 15,000 volumes (some rare and of great interest) and has been valued at more than 12,000*l.* It contains some rare books and receives more than 100 current periodicals in exchange for the society's journal. The council of the University has very gratefully accepted this magnificent offer, which will raise the medical library of the University to one of the most valuable medical libraries in the country. The advantage to the research worker of having access to such a library cannot be over-estimated.

CAMBRIDGE.—Mr. R. E. Priestley, Christ's College, has been elected to a fellowship at Clare College. Mr. M. C. Johnson, St. John's College, has been elected to the Arnold Gerstenberg studentship. Mr. N. J. T. M. Needham, Gonville and Caius College, has been elected to the Benn W. Levy research studentship in biochemistry.

The Syndicate appointed to draft Ordinances to carry out the provisions of the new statute admitting women students to the titles of degrees has been published. It is proposed to recognise Girton and Newnham Colleges as institutions for the higher education of women for the purposes of the statute. The total number of students at the two colleges (or at all institutions for the higher education of women, should any fresh college be recognised) who are receiving instruction in the University or working in the University laboratories or museums is not to exceed five hundred. The Council of the Senate may at any time inquire into the condition and management of a recognised institution for the higher education of women, and may, if it think fit, recommend the termination of its recognition. Women must reside nine terms, and in other such matters come under the same regulations as the undergraduates before admission to the titles of their degrees. Once the title has been conferred upon them, they become entitled to wear the same academical dress as that worn by a member of the University who has been admitted to the same degree. Women are to be admitted to courses of research and to examinations for diplomas sub-

stantially on the same terms as men. Residence already kept and examinations already passed will qualify past students for the same privileges as if the new regulations had been in force in earlier days

The *Times* announces a bequest by the late Mr A M. Shield of some 90,000*l* to the Cambridge Medical School. The only definite item mentioned is the foundation of a Marmaduke Shield scholarship of 100*l* a year in human anatomy

LEEDS.—The following appointments to the staff have been made by the Council of the University Mr R B. Tasker, honorary demonstrator in anatomy for dental students, Mr C Holland Child, Mr G H. H Russell, and Mr R B Tasker, honorary clinical tutors in dental surgery, Dr A C Monkhouse, research assistant in the fuel industries department, to work under the joint committee of the Institution of Gas Engineers and the University on gas heating, lighting and ventilation research, Dr E C Porter, demonstrator in the department of leather industries, Mr J C Mann, assistant lecturer in agricultural chemistry, Mr S J Saint, assistant lecturer in agriculture, Mr R E Edwards, demonstrator in agricultural botany; Mr J C. Leslie, district lecturer in agriculture, Mr. G F Pilling, assistant lecturer and demonstrator in agriculture, Mr H W Swift, demonstrator in engineering, Mr W A Wightman, demonstrator in organic chemistry, Mr Thomas Henderson, demonstrator in inorganic chemistry, and Miss E. M Hickman, demonstrator in the department of pathology and bacteriology

MANCHESTER -Applications are invited for the position of Keeper of the Museum in place of Dr W. M. Tattersall, now of the University College of South Wales, Cardiff The latest date for the receipt of applications, which should be sent to the Secretary of the Manchester Museum, is Friday, December 1

Provision has been made in the Faculty of Technology, which formerly awarded an ordinary degree of B Sc Tech, to give a higher B Sc Tech degree in various sections of technological science, one of which will be the chemistry of colouring matters

In view of the retirement of Prof H B Dixon from the chair of chemistry, a committee of past and present students are raising a fund to recognise his thirty-five years of distinguished service The fund is to be devoted mainly to the provision of grants to enable students of chemistry to complete their courses, and it is also intended to set up in the chemical theatre a plaque or bust of Prof Dixon These objects necessitate a generous response on the part of old students and colleagues of Prof Dixon, and those who have not yet subscribed are invited to send their subscriptions to Dr Norman Smith at the University A complimentary dinner will be held on December 8, further particulars of which can be obtained from Dr J E Myers

---

THE Association of Science Teachers and Association of University Women Teachers have organised a conference on the teaching of science in schools and colleges to be held on Saturday, November 25, at University College, London The opening speakers will be Sir William Tilden and Mr A G Tansley

THE Parliamentary candidates of University constituencies, for the general election on November 15, are as follows (the names of new candidates are in italics) Oxford (2)—Lord Hugh Cecil (U), Sir Charles Oman (U) Cambridge (2)—J F P Rawlinson (U); *Prof W R. Sorley* (U.); *J R M. Butler* (Ind) London.—*Sir Sydney Russell-Wells* (U.); *Prof A. F. Pollard* (L); *H. G. Wells* (Lab.). Combined English (Manchester, Liverpool, Durham, Leeds, Sheffield, Birmingham, and Bristol) (2) H A. L. Fisher (N L), Sir Martin Conway (U), *B Faraday* and *Dr. S Lawrence* (U), and *L Woolf* (Lab.). Wales.—*Sir E J Ellis Griffith* (L), *T A. Lewis* (N L.). Scotland (St Andrews, Glasgow, Aberdeen, and Edinburgh) (3) Sir Henry Craik (U), *Sir George Berry* (U), D M'Coig Cowan (N L) Queen's, Belfast —Sir William Whitla (U)

THE list of successful candidates in the open competition for Royal Scholarships and Free Studentships, 1922, just issued by the Board of Education, shows that in Group A (Mechanics) there were fifty four competitors, and of the nine scholarships and studentships awarded, six are to apprentices in H M Dockyard This is a remarkable testimony to the efficient educational work carried on in the dockyard schools, which all dockyard apprentices must attend for certain specified periods every week The number of competitors in the other groups of subjects in which scholarships and studentships are awarded were physics, 17, chemistry, 10, biology, 1, geology, no qualified candidates

NUMEROUS announcements of courses of technical education for 1922 23 have been received recently Courses of advanced study and training in research are offered by the Manchester College of Technology in many branches of applied science, including special problems connected with textiles, brewing and allied industries, paper-manufacture, photography, coal-tar, dyestuffs, and india-rubber The college awards annually a varying number of research scholarships (last year twelve) of 100*l* each, open to graduates of any university in the British Empire and to other persons suitably qualified A department of industrial administration has recently been opened. The Sir John Cass Technical Institute of Aldgate, London, invites special attention to its advanced courses (evening) in brewing, micro-biology, petroleum technology, colloids, alternating currents and electrical oscillations, metallography and pyrometry, heat treatment and mechanical testing of metals and alloys, and foundry practice The Northampton Polytechnic of Clerkenwell, London, has, in addition to its evening courses, day courses in civil, mechanical, including automobile and aeronautical, and electrical engineering, in optical engineering and applied optics, and in horology

THE Scottish Colleges of Agriculture maintain a close connexion with the regions which they serve by means of their systems of extra-mural work, including lectures and individual instruction, demonstrations and experiments, and advisory work The Calendar for 1922–23 of the Edinburgh and East of Scotland College mentions a notable development of work in connexion with school gardens which have been laid down under the guidance of the college staff at 196 schools Seven supplementary school centres are visited by the staff once a week for practical instruction in the school garden combined with theoretical instruction in the laboratory The Calendar of the North of Scotland College contains an account of the recently opened Rowett Institute for research in animal nutrition, and of an important research which is being conducted by Dr Rennie in regard to certain diseases of adult bees In the area served by this college, attendances at county extension classes increased during the past two years from three to eighteen thousand, while attendances at short courses of lectures and single lectures increased from fifteen to thirty-eight thousand Special schemes are arranged to meet the requirements of the crofting districts in the western seaboard and islands and in Shetland.

Calendar of Industrial Pioneers.

November 5, 1800. Jesse Ramsden died.—Called by Delambre "le plus grand de tous les artistes," Ramsden, by the combination of great scientific ability and practical skill, rose to be the leading instrument maker of his day. Especially valuable was his invention of a dividing machine completed in 1773 after ten years' work. He was born in Halifax, Yorkshire, in 1735, worked first as a cloth worker, and then learned the art of engraving from a London optician.

November 6, 1913. Sir William Henry Preece died.—Born in Carnarvon in 1834, Preece, after passing through King's College, London, joined the Electric and International Telegraph Company and eventually became one of the principal telegraph engineers in the country. From 1892 to 1899 he was Engineer-in-Chief and electrician to the Post Office, in which situation he made some of the earliest experiments in wireless signalling and gave valuable support to Marconi. He was twice president of the Institution of Electrical Engineers and was also president of the Institution of Civil Engineers.

November 8, 1807. Pierre Alexander Laurent Forfait died.—A distinguished naval constructor whose skill proved of the highest value to the French nation, Forfait first gained a reputation by the building of sailing-vessels for maintaining regular communication between France and America. He was the author of a treatise on the masting of ships and wrote many papers for the Paris Academy of Sciences and the "Encyclopédie Méthodique." He carried out important work at Antwerp and on the Seine, and under Napoleon served in the Ministry of Marine.

November 8, 1911. William Edward Ayrton died.—The author of some 150 scientific papers, a prolific inventor, and one of the pioneers of technical education in London, Ayrton served in the Indian Telegraph Service from 1868 to 1872, was professor of physics and telegraphy at the Imperial Engineering College, Tokio, and from 1884 held the chair of physics and electrical engineering at the Central Technical Institution, London. His researches extended to all sides of modern electrical engineering, while among the positions he filled were the presidencies of the Physical Society and the Institution of Electrical Engineers.

November 11, 1906. John Devonshire Ellis died.—Trained as an engineer at Birmingham by his father, Ellis in 1854 joined John Brown at the famous Atlas Works at Sheffield, with which he remained connected till his death. He was largely responsible for the manufacture of the armour for our first ironclads, the *Black Prince* and *Warrior*, and was an ardent advocate of the Bessemer process of making steel. He also introduced a method of welding a hard steel face to a wrought-iron backing for the armour of ships. He succeeded Brown as head of the firm in 1870, and in 1889 received the Bessemer medal of the Iron and Steel Institute.

November 11, 1893. Anthony Reckenzaun died.—A pioneer of electric traction, Reckenzaun was born at Gratz, Styria, in 1850, and, after being trained as an engineer, worked in England and was engineer to the Electric Power Company. In 1881 he made a trial of an electric car, in 1882 built the launch *Electricity*, and in September 13, 1886, with the *Volta* crossed the Channel, the motive power being obtained from electric cells. He also visited America and applied his system of driving by electric batteries to some cars at Philadelphia. E. C. S.

Societies and Academies.

LONDON

Association of Economic Biologists, October 13.—Prof. E. B. Poulton, president, in the chair.—E. J. **Butler**: Virus diseases in plants. The first demonstration that disease can be caused by a filtrable virus was by Iwanowski, in 1892, in mosaic disease of tobacco. Mosaic is now known in nearly 100 species of plants. Diseases like peach-yellows and others characterised by phloem-necrosis are probably caused by similar agents though the filtered juice is not infective. All hitherto tested can be transmitted by grafting, most of them by insects (the chief method in Nature), and many by inoculating with sap. Contact will not cause infection. Infection may be hereditary in the insect transmitter and in the plant. "Carriers" are known. The causal agents are believed to be living organisms. Several investigators have recently found large amoebiform corpuscles or smaller granules in infected cells. The former have been compared with cytoryctes or neuroryctes and the latter with Chlamydozoa but a resemblance to Rickettsia is suggested. The causal organisms appear to be obligate parasites.—J. A. **Arkwright**: Virus diseases in animals and man. The chief points of interest common to plant and animal "virus diseases" are (1) the nature and properties of the virus; (2) the means of transmission, *e.g.* "carriers" and insect vectors; (3) measures for prevention, *e.g.* breeding or selection, and isolation or destruction; (4) perhaps the concentration of the virus in certain special tissue cells. About fifty animal virus diseases have been described which may be roughly classified as follows: (1) visible, not filtrable, not cultivated, *e.g.* Rickettsia; (2) probably visible, filtrable, cultivated, *e.g.* pleuro-pneumonia of cattle, poliomyelitis; (3) filtrable, not cultivated, some (?) visible in the tissues, *e.g.* foot and mouth disease, vaccinia; (4) filtrable, very resistant, *e.g.* infectious anæmia of horses, fowl-pox. In general properties most do not differ much from bacteria though some are very resistant to drying, glycerine and heat. The smallest clearly visible and the largest filtrable particles are of the same order of size, *i.e.* about 0.2 micron. Living organisms may conceivably be much smaller than this. The differentiation of colloidal particles of about 0.2 micron in size by means of the microscope requires attention especially to their arrangement and their range of size and shape, rather than to the appearance of individual particles. Theoretically it is possible that an enzyme may be the cause of an infectious disease on the analogy of Twort's lytic substance and the bacteriophage of d'Herelle.

PARIS

Academy of Sciences, October 2.—M. Albin Haller in the chair.—H. **Deslandres**: The emission of X-rays, ultra X-rays, and corpuscular rays by the celestial bodies. A summary of previous results on radiation of high frequency and great penetration given by the sun and stars. These radiations form an extremely minute proportion of the total radiation, but their remarkable electrical properties give them an important rôle in the electrical phenomena of atmospheres. Kohlhörster's experiment on the ionisation of gas in a closed vessel at high altitudes (9000 metres) should be repeated at several points on the earth, and extended to the highest possible altitudes attainable by captive balloons. The cost will be considerable and international co-operation is suggested as desirable.—A. **Brachet**: The properties of the germina

localisations of the egg. The eggs of *Rana fusca*, after growth to the advanced blastula stage were pricked with a needle at various points. From the resulting modifications in the growth it can be concluded that the formative materials of the whole of the central nervous system and the dorsal chord are, in the blastula and consequently in the fertilised egg, localised in the zone occupied by the grey crescent.—Paul **Montel**: Quasi-normal families of meromorphic functions.—Eligio **Perucca**: The surface properties of mercury: voltaic character, surface tension, photo-electric effect. Measurements of the Volta effect and surface tension of mercury in a vacuum and in different gases at varying pressures show changes in both magnitudes which are in qualitative agreement with the anti-contact theory of Frenkel.—Jean **Durand**: Contribution to the study of the thermal modifications of some cast irons. A diagram is given showing the volume expansions and contractions produced in a fragment of cast iron by five successive heatings between 600° C. and 900° C. The swelling of cast iron becomes significant only if the proportion of silicon is sufficiently high and the heating is slow.—L. J. **Simon** and A. J. A. **Guillaumin**: The quantitative determination of carbon and of hydrogen by the use of chromic and sulphuric acids. The carbon is determined directly as usual and the hydrogen indirectly by measuring the amount of oxygen (derived from a weighed amount of potassium bichromate) used in the combustion. Analytical figures are given for ten organic compounds of different types.—A. **Brives** and M. **Dalloni**: The earthquake of August 25, 1922, and the geological structure of the region of Ténès-Cavaignac (Algeria).—René **Souèges**: Embryogenic researches on *Hippuris vulgaris*.—Marc **Bridel** and Mlle Marie **Braecke**: The presence of aucubine and of saccharose in the seeds of *Rhinanthus Crista-Galli*. The biochemical method of Bourquelot applied to Rhinanthus seeds indicated the presence of saccharose and aucubine, and both these substances were then isolated from the seeds in a pure state.—A. **Policard**: The mechanism of working of the adipose cells. The elaboration by the mitochondria represents only one of the possible modes of fixing fat; the adult cell takes up the fat by direct fixation without preliminary chemical change.—A. **Desgrez**, H. **Bierry**, and F. **Rathery**: Diabetes, β-oxybutyric acid, and levulose. A study of the conditions under which a certain quantity of levulose may be added with advantage to the diet of diabetic patients.—A. **Goris** and P. **Costy**: Urease and urea in fungi. Urease is present in nearly all the higher fungi. In cases where urease is absent, or present in very small proportion, urea has been found to be present.—Emile F. **Terroine**, R. **Wurmser** and J. **Montané**: The influence of the constitution of the nutritive media on the composition of *Aspergillus niger*.—Georges **Truffaut** and N. **Bezssonoff**: A new bacillus capable of fixing nitrogen. This organism was isolated from some cultures of Versailles garden s[illegible] and morphologically is connected with the [illegible]us group. This bacillus is aerobic and fixes [illegible] nitrogen. It appears to differ from the [illegible] assimilating nitrogen hitherto known, and it is [illegible]d to name it *Bacillus Truffauti*.—J. **Cluzet**, [illegible]haix, and Th. **Kofman**: The action of the [illegible]ry radiation of X-rays upon micro-organisms.

[illegible]er 9.—M. Albin Haller in the chair.—H. [illegible] The Lepidocyclines and their evolution [illegible]nus "Amphilepidina."—E. L. **Bouvier**: [illegible]rches on the appearance of reproductive [illegible] in the ants, *Formica rufa*, and *F. pratensis*.—Paul **Vuillemin**: The petalostem.—G. [illegible]: Progressions of higher order.—Halvor **Hansson**: A new method of multiplication of functional scales.—M. **d'Ocagne**: Remarks on the preceding communication.—Rodolphe **Soreau**: The laws of variation of the characteristics of standard air with altitude.—M. **Seigle**: The possibilities of the commercial use of mild steel bars hardened by extension. Details of the mechanical effects produced in mild steel bars by extension up to the breaking point have been given in an earlier communication. The advantages of this method of hardening are summarised and various possible industrial applications mentioned.—Charles **Nordmann** and M. **Le Morvan**: The effective temperatures of the stars θ and ϵ in the Great Bear. Reply to a criticism of Ejnar Hertzsprung on a previous communication.—Charles L. R. E. **Menges**: The coefficient of Fresnel.—G. **Holst** and F. **Oosterhuis**: The explosive potential of a gas. In Townsend's theory of ionisation by shocks the explosive potential depends only on the properties of the gas, and the material of the electrodes is without effect. The authors have proved experimentally that the nature of the cathode has an important influence. They support the hypothesis that the positive ions do not produce ionisation by contact with the gas molecules, but that by their electrostatic attraction they can liberate them from the cathode. A new theory of explosive potential is outlined, based on this hypothesis.—Jean **Rey**: The probability of illuminating an aeroplane by means of an electric projector.—André **Brochet**: Remarks on the preparation of cyclohexanol. Phenol containing 5 per cent. of its weight of reduced nickel as catalyst is readily reduced to cyclohexanol by hydrogen under pressure in an autoclave. The temperature should be maintained between 100° C. and 150° C. and the pressure kept at 10 to 15 atmospheres. The conversion is quantitative, and no indication was obtained of the formation of any intermediate compound.—A. **Damiens**: The absorption of ethylene by sulphuric acid. The production of ethyl alcohol, diethyl sulphate, and of liquid hydrocarbons. Cuprous oxide dissolved in the strong sulphuric acid proved the best catalyst. On hydrolysis, the acid solution gave different products with varying conditions. Absorption at ordinary temperature, with acid not under 97 per cent., gives ethyl alcohol only, but when a certain concentration of ethylsulphuric acid is reached, ethyl sulphate is also formed. At higher temperatures the velocity of absorption increases, and a considerable quantity of saturated hydrocarbon of the nature of petrol appears among the products of hydrolysis.—C. **Mariller** and Van **Ruymbeke**: A method for the preparation of commercial absolute alcohol and its application to the preparation of a national motor fuel. The vapours from 95 per cent. alcohol pass up a rectification column down which a stream of glycerol is descending. The latter removes water and the distillate contains 98.5-99 per cent. alcohol. The alcohol removed by the glycerol can be readily recovered.—Raoul **Combes** and Mlle Denise **Kohler**: The disappearance of hydrocarbons in dying leaves. When the leaves die in the autumn, about 45 per cent. of the carbohydrates remain in the fallen leaf and are lost to the tree; 35 per cent. disappear by respiration and only 20 per cent. return to the living parts of the tree and are retained in a form ultimately utilisable.—St. **Jonesco**: The transformation of a chromogen of the yellow flowers of *Medicago falcata* under the action of an oxydase.—Marcel **Mirande**: The relation between anthocyanine and the oxidases.—Léon **Azoulay**: Provoked and spontaneous movements of the leaves of *Russula Queletii* and its varieties.—P. **Mathias**: The evolutive cycle of a holostomid

trematode (*Strigea tarda*) — M Blanchard and G Lefrou A spirochæte found in the blood in a case of hæmoglobinuric bilious fever and its pathogenic action

Diary of Societies.

MONDAY, NOVEMBER 6

ROYAL INSTITUTION OF GREAT BRITAIN, at 5 General Meeting

SOCIETY OF ENGINEERS, INC (at Geological Society), at 5 30 —E E Turner The Atlantic Cruise of H M Airship R34

University Representation in Parliament.

THE last General Election was held in December 1918 under conditions entirely unfavourable for testing the revised system of university representation introduced by the Representation of the People Act of that year. Many thousands of the graduates of our universities were figuratively or literally removing from their minds and their habiliments the accumulated mud of four years' warfare. Women graduates, enfranchised for the first time both for university and for local constituencies, had been too much occupied with the problems, national as well as domestic, arising from the war to explore the new opportunities of social and political service which the hardly won privilege of the vote had earned for them. We need not attempt to examine in detail the political conditions which faced the nation at the conclusion of the war. Personalities and powers chose to act in accord with the transient temperament of a dazed and somewhat irresponsible people—a temperament which we now recognise, after four sobering years, was based on unsound economics and impracticable idealism.

If the lessons of the post-war period have been taken to heart, it is our duty in the present General Election to ensure, so far as possible, the return of members qualified by natural gifts, by training, by experience, to give to parliament expert and disinterested counsel, and to press for measures of reconstruction exhibiting sound and lasting principles. It is from this point of view that we propose to discuss the question of university representation. An old and peculiar element in our electoral system, the principle of university representation was before the war the subject of acute political controversy. Threatened with extinction, it has survived powerful and persistent attack, and, for reasons to some extent extraneous to the abstract merits of the case, has emerged from the war with enhanced prestige and extended application.

What, then, is the history and significance of university representation in parliament? Its originator, James I., was friendly disposed towards the ancient universities of Oxford and Cambridge, and indeed to universities in general, for he confessed that if he were not a king he would wish to be a university man. By letters patent under the Great Seal of England he commanded that two grave and learned men professing the civil law should be chosen by each university to serve as members of the House of Commons. In those days parliamentary representatives were usually chosen in pairs, possibly for mutual succour, and the representation of the ancient universities by two members each has remained undisturbed since the beginning of the seventeenth century. Originally the

enfranchisement of the universities was regarded as "a great favour to the universities as to the prosecuting their affairs in Parliament." This supposed benefit was soon recognised as to some extent illusory, for whereas under the old dispensation members who had been students of the universities "would stand up as occasion offered on behalf of their respective mothers," this duty was relegated to and, it is said, imperfectly discharged by the elected representatives of the universities. Candidly, we should find it difficult to justify the special representation of universities in the House of Commons if its sole object were deemed to be purely institutional, however important as national institutions our universities may be.

In pre-war days Mr. Asquith's complaint against university representation was that any constituency, whether you call it a university or anything else, will in the long run send to the House of Commons a man whose political opinions are in accord with the predominant opinions of those who sent him; and in support of this contention he was able to quote personal examples, particularly the treatment of Sir John Gorst by the University of Cambridge. This argument is not without weight, but it fails to demonstrate that a group of men and women of similar education and a common loyalty does not form as good a constituency for the election of a member of parliament as a group of men and women who happen to live in a selected locality such as South Kensington or East Ham. As Maitland points out, the ancient idea was the representation of communities, of organised bodies of men which, whether boroughs or counties, constantly met as wholes, and enjoyed common rights and duties. That system has given way as regards local constituencies to the representation of numbers, of unwieldy masses of men and women organised only for the purpose of choosing members. But this opens up a wide constitutional question which cannot be treated, adequately and appropriately, in these columns.

We prefer to base the case for university representation on Lord Balfour's argument that it is a method of getting into the House of Commons, men of science, men of scholarship, men of special and peculiar gifts quite alien from the ordinary working politician. The fact that university representation provides almost the last survival of plural voting enforces this argument. Representation of special interests in parliament may not be, in the abstract, desirable. Like the weather, it has to be accepted as a mysterious fact; and so long as labour, in a narrow sense, co-operation, "the trade," temperance, and many other interests are able to secure their representatives through the ordinary channels, we shall be well advised to implement the traditional method of securing the representation of science and education and the election to parliament of men and women whose lives have been consecrated, not to the study of the eclectic arts of the politician, but to the pursuit of truth and the advancement of learning. If this thesis be accepted, voters should strive to express in university elections the purpose and ideal which are inherent in this method of election.

Encephalitis Lethargica.

Ministry of Health. Reports on Public Health and Medical Subjects, No. 11. Report on Encephalitis Lethargica. By Allan C. Parsons; with contributions by Dr. A. Salusbury MacNalty and J. R. Perdrau. Pp. x+341. (London: H.M. Stationery Office, 1922.) 10s. net.

THE report on the subject of encephalitis lethargica, recently issued by the Ministry of Health, has a wider than medical interest, as illustrating the still considerable range of disease, of which our knowledge is so partial that preventive action is almost entirely impracticable.

This "new disease" appears to have been first recognised as distinct from other recognised diseases by Von Economo in Vienna in the year 1917. In the early part of 1918 cases were simultaneously reported in Sheffield and London, and prompt action for their investigation was undertaken by the Local Government Board, altogether some 230 cases being recognised during the first six months of that year. The symptoms of this disease, comprising somnolence, from which the patient is roused with difficulty, paralysis of ocular and other muscles, as their most marked features, bore some resemblance to those associated with botulism, and the first task of the earlier investigation was to eliminate the food poisoning to which botulism is due as a cause of the symptoms. This point the earlier official investigations definitely settled. A more difficult question was to decide whether—as was influentially urged—the disease was not a variant of poliomyelitis, which had been recently epidemic, especially among children.

The hypothesis that the two diseases both belonged to what is known as the Heine-Medin group, differing merely in the locality of the nervous lesions, was attractive; but for reasons detailed in the earlier governmental report and confirmed in the present report, this hypothesis, in the opinion of most observers, was satisfactorily eliminated. Similar considerations exclude influenza as a hydra-headed monster, with poliomyelitis and encephalitis lethargica as variants caused by the same virus. In Dr. Parsons' part of the present report the distinctions between these three diseases are judicially stated. Poliomyelitis prevails chiefly in late summer and autumn, encepha-

litis lethargica in the winter months of December to February inclusive. Poliomyelitis, unlike encephalitis lethargica, attacks chiefly children. Experimentally, the unidentified virus of each disease appears to be a filtrable organism, that of poliomyelitis being readily transmissible to monkeys; that of encephalitis lethargica being transmissible with difficulty and only from acute cases of the disease.

The detailed pathological and bacteriological evidence of the separate identity of these two diseases cannot be given here, but it is set out lucidly in Dr. MacNalty's contribution to the report under review.

The separate identity of influenza is sufficiently indicated by its proverbial infectiousness, whereas multiple cases of either encephalitis lethargica or poliomyelitis are a rarity. Even if it be assumed that the apparent partial non-infectiousness of these two diseases is due to the incarceration of the hypothetical influenzal virus in the deep parts of the central nervous system, it would still need explanation that the virus when introduced in these cases did not cause, *e.g.* in other members of the same family, ordinary attacks of influenza. There is no systematic parallelism in the prevalence of the three diseases; and as Dr. Parsons remarks, "the epidemic behaviour of influenza and encephalitis lethargica do not seem to represent a mutuality of any constant nature." The rarity of respiratory complications in cases of encephalitis lethargica is in itself a strong argument against community of origin.

The present reports by Dr. A. C. Parsons, Dr. A. S. MacNalty, and Dr. J. R. Perdrau, with a prefatory statement by Sir George Newman, bring our knowledge of this disease up-to-date. The value of the report is enhanced by an elaborate bibliography of 1243 items, which will be most useful to students of this obscure subject. The extent of incidence of the disease may be gathered from the statement that in 1919, 541 cases, and in 1920, 890 cases were recognised and notified, and it is not without significance that cases of poliomyelitis became much fewer in the same period. This may be explained on the supposition that a common virus at different times strikes at different parts of the nervous system; but the totality of evidence, epidemiological, clinical, and pathological, points in another direction.

We began this necessarily sketchy review with a statement that the group of diseases mentioned above do not yet come within the range of practical preventive medicine. When the agitation in one of our chief daily journals in favour of the much-needed Ministry of Health was at its height, the failure of the Local Government Board to control the pandemic of influenza was a big item in the indictment against it. This report, like the recent official report on influenza, should give pause to those who anticipate that uncontrollable diseases will be made controllable by changing the name of a government department. It has to be confessed—and from a scientific point of view it is most important to face the fact—that "respiratory infections" like influenza and (presumably) poliomyelitis and encephalitis lethargica are almost entirely uncontrollable, and will remain so until some new method of securing immunity is discovered, or until a standard of hygienic precautions is reached in respect of coughing, and even of speaking, which is not likely to be attained universally in this century. Even were it attainable would life then be tolerable?

Meanwhile, every channel of investigation needs to be pursued; and a word of praise may be given in this connexion to the wisdom of making encephalitis lethargica notifiable in 1918 as soon as its separate existence was fairly well established. By this means it has become practicable to investigate each notified case and to demonstrate the general absence of personal infection from recognised cases. By implication we are led to infer that slight unrecognisable cases of the disease exist which cause its spread; but this fact further emphasises the uncontrollable character of the disease in present circumstances.

Encephalitis lethargica has been described above as a "new disease." This merely means that it is a newly recognised disease. Crookshank and others have searched older literature and found descriptions which tally with this disease, occurring commonly in association with epidemics of influenza; and there can be little doubt that the apparent strict modernity of encephalitis lethargica is indeed apparent and not real.

The Telescope.

The Telescope. By Dr. Louis Bell. Pp. ix+287. (London: McGraw-Hill Publishing Co., Ltd., 1922.) 15s. net.

INVENTION is not the prerogative of the learned. The telescope, we are told, was the creation of the two little children of an observant father, a spectacle-maker of Holland. But, however casual the origin, its development was the result of laborious and progressive experiment and study, an excellent account of which is given by Dr. Louis Bell in the introductory chapter of the work before us.

There are partisans who will dissent from some of the author's historical statements, and many who will object to the presentation of Newton as a "blunderer," a "bungler," and a man who promptly jumped to a conclusion. As a boy, Newton tested the wind by jumping with and against it, and Sir David Brewster remarks: "This mode of jumping to a conclusion, or reaching it *per saltum*, was not the one which our

philosopher afterwards used." Dr. Bell has the same authority for the statement that, when investigating the relationship of dispersion to mean refraction, Newton mixed sugar of lead with the water. Traced to its source, however, this so-called fact appears to be merely a suggestion of Mr Michell, a friend of Dr Priestley, offered as an explanation of an otherwise inexplicable experimental result and based on Newton's use of *saccharum saturni* in other experiments

Flint glass good enough for quantitative observation could scarcely have existed in 1666, for about a hundred and forty years elapsed before Guinand resolved the optical glass problem It was more the absence of suitable material that "delayed the production of the achromatic telescope by some three-quarters of a century" than any action of Newton Indeed, Sir Isaac Newton should be honoured for his prescience in recognising that in the circumstances the practice of astronomy could best be advanced by the development of the reflector.

"The Telescope" has been "written for the many observers who use telescopes for study or pleasure and desire more information about their construction and properties," the information hitherto published on the subject being "for the most part scattered through papers in three or four languages and quite inaccessible to the ordinary reader" Within the limits of a single volume the author has collected a great deal of essential information that the general reader will find both useful and interesting

Following the historical introduction there are chapters on the modern telescope, optical glass and its working, properties of objectives and mirrors, mountings, eyepieces, hand telescopes and binoculars, accessories, the testing and care of telescopes, setting up and housing, seeing and magnification, and finally, a brief appendix on work for the telescope

The book is not free from mistakes In the description, for example, of the Galilean glass, the field is stated to be approximately measured by the angle subtended at the centre of the objective by the pupil The description given in "The Telescope" by Herschel, although theoretically incomplete, might have been copied with advantage, as it explains how the field is determined by the diameter of the objective and the possible displacement of the eye In chapter 7 the so-called Dove prism system is described as the rudiment of the prism binocular or shortened telescope. Such a system, unlike the earlier Porro combination, cannot be placed in the convergent beam and it cannot serve to shorten the telescope

Those to whom style and composition are of importance will regret the inelegance of such expressions as "credulous twaddle," "pricked up its ears," and "blast of hot air." Their use detracts from the pleasure of perusal of a welcome addition to the literature of the telescope. JAMES WEIR FRENCH.

An Elementary Work on Coal-Mining.

An Elementary Text-Book of Coal-Mining By Robert Peel Revised and enlarged by Prof. Daniel Burns. Twentieth edition Pp. viii+420. (London and Glasgow Blackie and Son, Ltd, 1922) 6s net.

THIS little book is, as its title expresses, a book dealing with the most elementary principles of coal-mining It has obviously answered its purpose extremely well, and has suited the needs of those to whom it is particularly addressed, as is only too evident from the fact that it has reached its twentieth edition since its original publication twenty-nine years ago. It need scarcely be said, therefore, that the general arrangement and style of the work are beyond criticism, otherwise it would not have survived the rigorous test of experience through which it has passed. Any review of the work must therefore be based upon the nature of the revision to which it has been subjected.

It may fairly be said that the labour of revising such a work falls under three main heads, namely, first to eliminate all possible blunders; secondly, to bring the work thoroughly up-to-date, and thirdly, to see that there is no ambiguity likely to puzzle the student Unfortunately, it cannot be said that the revision stands the test under any of these three heads, and a couple of illustrative examples of shortcomings may be quoted under each There are, for example, blunders in spelling, such as "Plammeller" for "Plenmeller" and "Maudline" for "Maudlin" Under the second heading we have such statements as that the deepest borehole in the world is that at Schladebach, which attained the depth of 956 fathoms. This was true once, but the deepest borehole in the world to-day is that at Czuchow, Rybnik, Upper Silesia, which has attained a depth of 7350 feet Again, the statement that of centrifugal fans those most generally adopted are the Guibal, Waddle, and Schiele was true once, but is not true to-day The only reference given to the Kind-Chaudron method of sinking in this country is its first application at Marsden, the far more important, instructive, and recent sinking at Dover not being mentioned Under the third head we get such a statement as that when it is inconvenient to state work in foot-pounds as the unit of work a higher unit is adopted termed horse power. The confusion between work and power, to which most students are prone, is one that should never be allowed to creep into a text-book, where the difference between the two standards should be very clearly explained. Again, in dealing with the thickness of tubbing, two

formulas are given, one due to Greenwell and the other to Aldis; an example is given of the use of the former, which is here worked out, giving a thickness of 1·19 inches; if the reviser had worked out the same example by the second formula here given, he would have obtained a thickness of 1·98 inches, yet no hint is given to tell the student that the two formulas do not agree, or to help him in any way to reconcile so grave a discrepancy.

It is also a pity that so many of the illustrations are mere sketches, and badly executed at that. As an example Fig. 104, which is intended to be the plan of a horizontal winding engine, may be quoted; an intelligent boy of twelve who had seen a winding engine would probably in his drawing indicate that there are such things as valves and valve-rods.

It has been thought advisable to direct attention to the points in which this little book falls short of the standard to which it might so easily be raised, because, as already stated, it has evidently a very decided sphere of usefulness, and in a work of this kind addressed to the beginner it is pré-eminently necessary that he shall receive no wrong impressions and shall be left with nothing to unlearn when he advances to the higher stages of the subject.

Essays on French Science.

Discours et mélanges. Par Emile Picard. Pp. x+292. (Paris: Gauthier-Villars, 1922.) 10 francs.

THIS volume contains discourses, short essays, and obituary notices of some distinguished French men of science. It may be warmly recommended, more especially on account of the obituary notices, which do not confine themselves—as is too frequently the case—with an account of the work done, but tell us something of early surroundings, education, and temperament, and thus bring out the personality as well as the results achieved. It is not only that the account gains in interest thereby, but the information allows us to judge more adequately of the individual influence exerted on contemporary science.

Pierre Duhem's work is recognised in this country by every one familiar with thermodynamics, but the personal touches which M. Picard's account supplies give us just what is wanted to appreciate the full value of the man. Poincaré is better known to us, perhaps Darboux also, but we shall find here something new about them as well as about others with whose work M. Picard deals. The notice of Lord Kelvin is excellent.

The author does not always confine himself to those branches of science which he has himself enriched by valuable contributions. As secretary of the Academy of Sciences he has to undertake the duty of explaining the ground for the award of prizes, some of which, like that founded by Mr. Osiris, include a wide range of subjects. We thus find short discourses on "French Aviation in 1909," and even on "Antityphoid Vaccination." A lecture on the diminution in the birth-rate was no doubt inspired by the atmosphere of the war, and some of the other writings are even a more direct outcome of the anxieties of the time at which they were written. Here it is perhaps allowable to make one criticism. In the essay on "Les Sciences mathématiques en France," M. Picard shows so much knowledge of scientific history in other countries and such fair appreciation of the international aspect of science, that one regrets the inclusion of an article that originally appeared in the *Revue des Deux Mondes*: "L'histoire des sciences et les prétentions de la science allemande." There is no doubt much in it that is true, but it is not written in the dispassionate and eminently fair spirit which pervades the rest of the book and it strikes a discordant note.

Graphical Methods in Crystallography.

Graphical and Tabular Methods in Crystallography as the Foundation of a New System of Practice. With a Multiple Tangent Table and a 5-Figure Table of Natural Cotangents. By T. V. Barker. Pp. xvi+152. (London: T. Murby and Co., 1922.) 14s. net.

IT has been anticipated for some time that Mr. Barker would publish an account of the graphical and tabular methods in crystallography which he has been teaching at Oxford, and that his book would include a description of the form of two-circle goniometry and its special application to crystallochemical analysis, which he recommends as the result of his studies in Russia under the late Prof. Fedorov. The present volume only very partially fulfils these expectations, crystallochemical analysis being reserved for a further publication. So far as it goes, however, the book is a valuable presentation of extant graphical methods, and it concludes with a most useful table of multiple tangents.

The main purposes of the monograph are "to provide the researcher with a select collection of exact graphical methods, which personal experience has proved to be both accurate and time-saving; to discuss the relation of these methods to formal processes of computation; and, finally, to outline a new system of practice." The methods described involve the use of both the stereographic and gnomonic projections, and are a mixture of the well-known ones due to Penfield, Hutchinson, V. Goldschmidt, and Fedorov. A crystallographic protractor is described and recommended, which in itself is a happy combination of the features of the Penfield, Fedorov, and Hutchinson protractors.

U I

The new system of practice, which forms the subject of the last chapter, is obviously chiefly concerned with rapid (time-saving) work, with a view to the inclusion of some crystallographical account of all new substances, as well as existing ones, in a comprehensive catalogue, or to the identification of a crystallised substance by the comparison of such rapidly acquired data with that contained in such a compendium of measured substances. Two-circle methods are used, and the table of angles characteristic of a substance consists of the theodolitic ϕ azimuth and ρ altitude values. It is suggested that "two, or at most three, crystals be measured," that "the indices be determined by a time-saving method," that "the mean observed angles be published without any citation of limits," and that "the practice of computing theoretical angular values (apart from those involved in the elements) be discontinued." This may satisfy Mr. Barker, and may possibly be adequate for the particular purpose which he has in view. But it is most sincerely to be hoped that serious crystallographic research is not to be so circumscribed, and that absolute accuracy will be placed before time-saving. Otherwise we shall rapidly revert to former chaos. It has been, indeed, only by the most accurate and laborious work, in which time was regarded as subservient to the highest accuracy, that the subject has been brought to its present high position, this alone has rendered possible the wonderful confirmation, by the absolute measurements now made by the Bragg X-ray spectrometric method, of the work of the later crystallographers.

Our Bookshelf.

Magnetism and Electricity. By J. Paley Yorke. New edition, completely rewritten. Pp. viii+248. (London: E. Arnold and Co., 1922.) 5s. net.

WRITTEN in colloquial language, this book, which is a first-year course on magnetism and electricity, will appeal to many beginners besides the students in technical institutions, for whom it is primarily intended. "These students have one great quality: they are out to learn and to understand, and as they are not hampered by the immediate necessity of cramming for any particular examination, are able to enjoy the pleasures of understanding instead of suffering the terrors of memorising. . . . Memory is useful for examinees, but understanding is essential for engineers." There is abundant evidence throughout these pages that the author is familiar with the difficulties met with by the beginner, and he is always careful to explain the technical terms which are apt to be used freely by text-book writers who have almost forgotten that their jargon is not that of the man in the street. Magnetism is first dealt with, and then the ideas of static and current electricity are introduced. The author is particularly successful in developing the self-contained water circuit analogy, the basic idea of which is that energy can be distributed without any consumption of the water. Experience has convinced him that the plan of introducing the measurement of electrical energy at an early stage is very effective. The basic ideas of electro-magnetic induction are discussed in some detail, and in the final chapters the phenomena of electrostatics are briefly treated. We can recommend the book to those for whom it is intended, but fear to think what the modern relativist would have to say to such statements as, "Anything which has weight is called *Matter*: magnetism is therefore not matter" (page 21); "This something which is called energy has not got weight" (page 57)!

The Climates of the Continents. By W. G. Kendrew. Pp. xvi+387. (Oxford: Clarendon Press, 1922.) 21s. net.

MR. KENDREW strikes new ground by giving a description of the actual climates of the regions of the world. The scope of the treatment must naturally vary with the nature of the original sources which are available, but no detailed local descriptions are attempted. A general knowledge of meteorology is assumed. There is no explanation of the omission of polar climates, north and south. Quite enough is now known of these climates to enable useful accounts to be included in a book of this sort. The oversight mars the usefulness of the volume. We notice that Mr. Kendrew adheres to the idea that the heating of north-west India furnishes an explanation of the south-west monsoon. The comparatively poor rainfall in the north-west he attributes to the previous course of the winds reaching that region, which has deprived them of much of their moisture. According to Dr. G. C. Simpson, the explanation is far more complex, and depends on several factors, of which one of importance is the dry upper-air current from the west, which prevents cloud formation in the ascending air. These and other recent theories regarding the monsoon are not discussed by Mr. Kendrew. There are many clear diagrams and maps, and numerous meteorological data. All students of geography will be grateful for this well-arranged and lucidly written volume.

Miracles and the New Psychology: A Study in the Healing Miracles of the New Testament. By E. R. Micklem. Pp. 143. (London: Oxford University Press, 1922.) 7s. 6d. net.

THIS work is concerned with a comparison between the healing miracles described in the New Testament and the case records of modern psychotherapy chiefly drawn from war practice. A brief description of modern psychotherapeutic measures is given, but the complexity and difficulty of the subject almost necessarily makes such a sketch confusing to the uninitiated reader. The sources of the New Testament narratives are examined and the inexactitude of observation is commented upon, especially in the fourth gospel. The current superstitions anent the relationship of sin and disease and demonology are noticed as likely to colour and detract still further from the trustworthiness of the descriptions.

The miracles are then dealt with *seriatim*, and where possible, recent parallel cases are quoted. Finally, the author disclaims the belief that all the subjects of the

healing miracles were suffering from what would now be called functional disease, but seeks to support his thesis that these works of Christ were in accordance with natural laws, by quoting cases (not always convincing) of the effect of psychotherapy on organic disease.

The general impression of the book is that while the author has made out a plausible and even probable argument that the miracles were not supernatural phenomena, his parallels are not sufficiently exact to carry absolute conviction. Such exactitude could never be obtained in view of the unscientific observations of the New Testament cases by men who certainly thought these works were supernatural and were quite untrained in medical knowledge. As the author points out, even Luke "the physician" uses terms rather less exact from the medical point of view than do the others. The book is certainly readable and interesting, but belief that the ministrations referred to in it were miraculous is not likely to be disturbed by the author's scientific consideration of the evidence upon which it is based.

A Book about Sweden. Pp. 183. (Stockholm: A.-B. Nordiska Bokhandeln, 1922.) n.p.

WE have received through the Swedish Consulate-general in London a copy of "A Book about Sweden," published in Stockholm by the Swedish Traffic Association. It is a compact guide, very fully illustrated, written in English for those who may wish to visit Sweden, or for those who have not yet realised what a charming and novel field awaits the tourist, accustomed to think of Europe as centred in Grindelwald or Assisi. The photograph of the s.s. *Saga*, now running between London and Gothenburg (Göteborg), invites the Englishman by a reminder of his Viking blood. The description of the country and its human occupations is geographical, and many of the views, such as those in Lappland, are difficult to obtain from other sources. That of the iron-mountain of Kiruna, lit up electrically for work in the long winter night, illustrates one of the great romances of Swedish industry. The account of power-developments in general will interest scientific readers. We are shown the fascination of Abisko, remote within the Arctic Circle; but nothing is said about the summer mosquitoes, and the happy tourists at Tornetrask seem to be going about unveiled. The manifold charm of Stockholm, a city unlike any city, the sweet clean beauty of the forest country, the rush of waters at Porjus and Trollhattan, are here simply set before us. If one knows Sweden already, it is all the more delightful to turn these pages, and, as the Dalarna poem says, to long for her again. This little handbook may be recommended to British teachers of geography. G. A. J. C.

14,000 Miles through the Air. By Sir Ross Smith. Pp. xii + 136. (London: Macmillan and Co., Ltd., 1922.) 10s. 6d. net.

THIS small volume by the late Sir Ross Smith marks an epoch in the history of flying, for it is a record of the first flight from London to Australia. Sir Ross Smith and his brother, Sir Keith Smith, accompanied by two air-mechanics, Sergeants J. M. Bennett and W. H. Shiers, entered a Vickers-Vimy aeroplane for the prize of 10,000*l.* offered by the Commonwealth Government in 1919 for a flight from England to Australia in 30 days. As is well known, the two brothers won the race. They left Hounslow on November 12, 1919, and reached Darwin on December 10, 1919. From there the flight was continued to Sydney, Melbourne, and Adelaide. The actual time spent in flying between London and Adelaide was 188 hours 20 minutes. The longest spells in the air were 730 miles from Bundar Abbas to Karachi, and 720 miles from Karachi to Delhi. The brevity of the book makes it all the more vivid, and helps the reader to realise the speed of travelling by air. The author gives few incidents and certainly dwells lightly on the difficulties encountered. But there are some exciting passages, of which one of the best is the flight through the clouds between Rangoon and Bangkok, and the groping descent with the fear of collision with the heights of the Tenasserim Ranges. The book is well illustrated, the pictures of cities taken from the air being very striking. It is much to be regretted that this high-spirited airman lost his life at the very start of his next great adventure, a few years later, of the flight round the world.

Evolutionary Naturalism. By Prof. R. W. Sellars. Pp. xiv + 349. (Chicago and London: The Open Court Publishing Co., 1922.) n.p.

THE author of this book is one of the "critical" realists. The difference between a neo-realist and a critical realist would seem to be that the former regards the datum of perception as identical with the object of knowledge, while the latter distinguishes between them. The neo-realist says that we know the physical existence in perceiving it, the critical realist says we know the existence of the physical thing but what we perceive is its essence. Objects exist, but only their content and not their existence is perceived. The special theory which Prof. Sellars names evolutionary naturalism is based on this distinction. Its two great enemies, we are told, are Platonism and Kantianism, both of which are supernaturalistic. The theory is worked out in laborious detail and applied to the different problems of philosophy.

Greek Biology and Greek Medicine. By Dr. Charles Singer. (Chapters in the History of Science, I.) Pp. 128. (Oxford: Clarendon Press, 1922.) 2s. 6d. net.

DR. SINGER here gives a succinct account of the general evolution of Greek biological and medical knowledge. The biological portion of the book is arranged in three sections, "Before Aristotle" (18 pp.), "Aristotle" (36 pp.), and "After Aristotle" (24 pp.); the remaining 50 pp. being allotted to Greek medicine. The section on Aristotle appears here for the first time; the others are reprinted, with slight amendments, from "The Legacy of Greece." All who are interested in the biological sciences will be glad to have in this cheap and convenient little volume an authoritative account of the works of Aristotle, Galen, Hippocrates, and others who laid the foundations of the science of life; and the majority of readers will be amazed at the extent of our indebtedness to Greece.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Structure of the Red Lithium Line.

IN a recent number of the Proceedings of the Royal Society Prof. McLennan and Mr. Ainslie have announced the interesting discovery of a new component of the line λ 6708 in the spectrum of lithium, the line appearing, under the conditions of excitation employed by them, as a quartet. They proceed to discuss the possibility of this structure being due to two pairs of lines, each pair being assigned to one of the isotopes of lithium. To the present writer it appears that the new components cannot be accounted for in this manner.

The structure of the line in question has been investigated by Kent (*Astrophys. Journ.* vol. 40, p. 337, 1914), Takamine and Yamada (Proc. Tokio Math. Phys. Soc., vol. 7, No. 18, p. 339, 1914), Zeeman (Proc. Roy. Acad. Amsterdam, p. 1130, Feb. 1913, p. 155, Sept. 1913), King (*Astrophys. Journ.*, vol. 44, p. 169, 1916), and the writer (Proc. Roy. Soc. A, vol. 99, p. 101, 1921). Kent, and Takamine and Yamada, observed it as a single pair of emission lines, and Zeeman, who investigated the absorption spectrum, also recorded a single pair of lines, with the reservation that with a high density of the absorbing vapour other lines made their appearance. Zeeman considered that these lines which appeared at high vapour densities were analogous to lines observed in the sodium spectrum by R. W. Wood. King, who investigated the structure of the line in the arc and in the tube-furnace, found that with a low vapour density the line appeared as a simple pair, and that at higher vapour densities a third component appeared; with a still greater amount of vapour the phenomena were complicated by reversal. King has published one photograph in which, owing to reversal, the line has the appearance of a quartet. McLennan and Ainslie used a vacuum arc under conditions in which it would appear that the density of the lithium vapour must have been very great, and one may surmise that this condition is essential for the appearance of the fourth component.

It seems, however, that under appropriate conditions the line appears as a simple pair, and our ideas as to the nature of isotopes would have to be profoundly modified if the pairs due to the two isotopes were found to require different conditions for their excitation. If the four components were really two pairs due to the two isotopes they should always appear together with an invariable intensity ratio of 1 : 16. The line can be seen easily as a simple pair in a carbon arc in air if the poles are brushed over with an exceedingly dilute solution of a lithium salt. The components are then less sharp than when the vacuum arc is used, and the main difficulty is to have little enough lithium in the arc, so as to avoid the appearance of the third component and complex structures due to reversal. In the vacuum arc the third component appears very readily unless the amount of lithium vapour is small. It may further be mentioned that the relative intensities of the components are not in good accordance with the view that they are due to the two isotopes.

From a theoretical point of view also, there are grave difficulties. The calculated separation, on Bohr's theory, of corresponding lines in the pair, is about 0.087Å., the observed separation being between three and four times as great. McLennan and Ainslie put forward the suggestion that the separation may in fact be the product of the "calculated separation" and the atomic number, but the correctness of the calculated separation has been verified by the observed differences between the lines of the Balmer series of hydrogen and alternate members of the ζ Puppis series of helium, and in this case the agreement is exact and the "calculated separation" does not require to be multiplied by a factor of 2, the atomic number of helium.

October 19.

The Mechanism of the Cochlea.

IN view of the discussion in these columns towards the end of 1918, and the letters which followed it at various times, the model designed by Mr. George Wilkinson, of Sheffield, and described in NATURE of October 21, p. 559, is of much interest and importance. It is obvious that the construction of such a model presented many mechanical difficulties, and great credit is due to Mr. C. E. Stewart, the mechanician of Prof. Leathes's laboratory, for the successful result. It may, therefore, be useful to mention that a full description was published in the *Journal of Laryngology and Otology*, of September last, a short account having been given in the Proceedings of the Physiological Society (*Journal of Physiology*, vol. 56, p. ii). The apparatus was demonstrated to the Physiological Society in December 1921, as also to the British Association in September 1922.

I take it that others besides medical students have been dissatisfied with most of the theories put forward to avoid the difficulties thought to be involved in the Helmholtz view of the resonance of the basilar membrane. Those theories in which this membrane is supposed to act as a whole, like a telephone diaphragm, or by "pressure patterns," are inconsistent with the progressive differentiation of structure along the membrane, in addition to being in conflict with what is known of the conducting properties of nerve fibres. Thus the views suggested by Ewald, Rutherford, Waller, and Wrightson are unacceptable. It appears that although Helmholtz had referred incidentally to "loading" of the vibrating elements of the membrane by the liquid in which it lies, the great importance of this factor was first realised by Mr. Wilkinson and investigated experimentally by him. His model is doubtless capable of still further improvement, but even in its present form many problems would have light thrown upon them by its behaviour. The degree of damping and the spread of resonance to neighbouring elements may be mentioned. The number of waves required to excite sympathetic resonance of a tuned element may perhaps be determined. Some degree of spread is not inconsistent with the Helmholtz theory, since the amplitude of vibration of other elements than those in tune with the vibrations received might well be too small to stimulate the nerve endings. Dr. Gray has shown that a similar cutting out of small stimuli takes place in the localisation of a point of pressure in the skin.

It is of interest to note that the model responds to a tuning-fork held in contact with the brass case, just as the cochlea does to conduction through bone. This indicates that the impulses given by the movements of the stapes are the same as those of sound waves directly transmitted through water, as would be expected from theoretical considerations.

Mr. Wilkinson also points out in his paper the necessity for the basilar membrane being continuous. If the fibres had gaps between them, no regular loading of the vibrating elements would be possible.

THE description of Dr. Wilkinson's model of the cochlea in NATURE (October 21, p. 559) recalls Dr. Yoshii's experiments on guinea-pigs. Yoshii operated with long-sustained notes from whistles of different pitches, and concluded from the resulting lesions in the organ of Corti that the pitch of the note determines the region of maximal displacement of the basilar membrane. But as he used the same pressure to blow the different whistles (*Zeitschr. f. Ohrenheilkunde*, 58, 1909, p. 205), the product a^2n^2 had a constant value, *i.e.* the greater the frequency of the note employed, the less the amplitude of its vibrations, which shows at once that Yoshii's results do not support his conclusions. If Dr. Wilkinson's model of the cochlea is a good one, it will show that the locus of maximal vibration in the basilar membrane for a given note shifts toward the distal end when the intensity of that note is increased, and toward the fenestral end when its intensity is diminished; and will thus demonstrate once again that the principle of resonance can find no application in the internal ear.

An Empire Patent.

IN the article appearing in NATURE for September 30, p. 437, with the above heading, there is the underlying assumption that the status of the inventor should be assimilated to that of the author, namely, that both should be secured a world-wide monopoly at a minimum expenditure. Will you allow me to present in your columns a more philosophical view of the history and function of patent law in relation to the growth and decay of civilisation, from which it will be seen that the favourable treatment of the inventor cannot be based upon international principles. It is part and parcel of a purely national and competitive policy.

The processes by which the characteristics of a higher civilisation are transmitted to races of lower culture appear to be based ultimately upon biological laws. Pressure generated within the walls of the higher civilisation drives out its more enterprising citizens to seek their fortunes elsewhere, and the new colonists, by interbreeding with the native stock, impart to it their own superior characteristics. The outward forces tending to the disruption of the older organisation may be economic, religious, or political, or some combination of these. The process may occupy centuries or be accomplished within as many decades. Thus the industrialisation of the English occupied many centuries—the periods of advance in the reigns of Edward III., Elizabeth, and Charles II. being associated with large influxes of the industrial population of the Continent. On the other hand, the rapid rise of the United States to the rank of a first-class power has been the work of the past fifty years. In both these instances national development was preceded by conditions which favoured the introduction and assimilation of a higher strain from abroad. Maintaining a civilisation at a high level in turn rests upon its compliance with the same biological law.

Talent and enterprise are the natural monopoly of a relatively small fraction of the human race. These characteristics are transmitted by direct descent, reproducing themselves in successive generations. How closely the fortunes of an industry may be associated with particular family names—notwithstanding the dilution which each family undergoes by marriage—is not sufficiently recognised. It has, for example, been shown recently that iron founding was introduced into this country by a body of French workers in the reign of Henry VII. A leading family which came in at this period were the Leonards, members of which migrated to the United States in the seventeenth century; whence the saying arose, that "where you find ironworks there you find a Leonard." But there is some reason to suppose that the French iron-founders originally came from Italy. Hence the Leonardos, Lennards, or Leonards may trace their connexion with this industry perhaps for 500 years. This reappearance of the same characteristics in successive generations of a family, and the predominance of the imported families in the higher ranks of culture—other than that of administration—can be verified by reference to the National Directories. A Stirling is generally an engineer, a Hochstetter a mineralogist, a Matthiessen a physicist. These families form a cosmopolitan body whose services can be enlisted by any country which possesses the power and foresight to attract them. Thus the maintenance of a civilisation depends upon its power to retain the services of its best native stock, while constantly reinforcing it from outside sources.

At an early period in the history of this country, bringing in companies of skilled artisans from abroad became an accepted feature in the exercise of the Royal prerogative. In the reign of Elizabeth a new feature was introduced, whereby, in addition to the Royal protection and favour, an exclusive right of manufacture was granted to any institutor of a manufacture not in use within the realm at the date of the Letters Patent. This system, though opposed to the tenets of the Common Law, received a grudging recognition in the Statute of Monopolies in 1624. Under this Statute the rights of the native inventor rested on the fact of his profession that he was willing and able to institute a new industry. The efficacy of the law rested upon two principles: that it attracted foreign strains of inventive ability, while stimulating that of the native inventor. Anthropologists are agreed that there is a fairly equal distribution of ability in different races. The English Crown recognised the deficiency in native stock and made good its defects by selective racial interbreeding.

The first blow to the efficiency of the English patent system was struck in the last quarter of the eighteenth century by a judge of the King's Bench. It is well known that there is a remarkable hiatus in the continuity of patent law decisions for the century and a half subsequent to the Statute of Monopolies. The reason for this is now clear. The Crown, notwithstanding the provisions of the above Statute, successfully maintained the right of disposing of its own grants by constituting the Privy Council the Court before which alone the validity of patent rights could be adjudicated. In spite of the more than doubtful character of its jurisdiction, the Council proved a most competent and business-like tribunal. It never lost sight of the real object of the law. Hence proposals for instituting new industries were not allowed to drop if a suitable applicant for the

privilege was forthcoming. The rights of the native workman were carefully respected. Occasionally technical points of law were reserved to the Common Law Courts, and in exceptional cases parties were allowed to seek their legal remedy; but in only one doubtful case during this period has any decision of the Courts found its way into patent jurisprudence.

With the Hanoverian dynasty the zeal of the Council in prosecuting its industrial policy sensibly abated, and about 1750, after an unseemly squabble between Lord Mansfield and the Privy Council, the jurisdiction of the Council was allowed to lapse. Thus when the Common Law Courts resumed their jurisdiction over Letters Patent they were without precedent to guide them for a period of about a century and a half

It was in these circumstances that the well-known doctrine of the patent specification was evolved Interpreting the Statute of Monopolies by the contemporary meaning of its language, the Courts construed the phrase "true and first inventor" in its modern sense This left the Statute devoid of any expressed consideration, for it invested the inventor with rights without any corresponding obligation True there was a clause in the Letters Patent of recent introduction which made the validity of a patent contingent upon the filing of a specification within a fixed period, but there was also an older final clause waiving a full, or indeed any, disclosure. By emphasising the former and ignoring the latter clause, Lord Mansfield laid down that the patent grant was made in consideration of the filing by the patentee of such a description of his invention as would enable a skilled artisan in the trade to work the invention The effect of this judgment was to make the validity of patents conditional upon their compliance with an uneconomic and, from an administrative point of view, impracticable standard of novelty; for the decision involved the shifting of novelty from the practice of the trade to novelty of disclosure within the realm By depreciating the security of the patent it lowered its commercial value—while discouraging the importation of industries not practised within the realm As, however, no attempt was made to bring administrative practice into harmony with the legal requirements, applicants continued to obtain their patents on the old basis

In 1905 a fifty years' search through British patent specifications came into operation It was instituted as an instalment of a wider scheme of examination to be introduced at a future date. The effect of official examination is always to reduce the restraining power of a monopoly in a degree corresponding with the extent of the search. A representative of one of the largest patent-owning firms in the United States once said to the present writer, "Our American patents are not worth a d—n! We take them out because they are cheap!" Without applying this dictum wholesale as a criterion of the value of the patents issued by any office which examines for novelty, it is clear that the effect of official examination is to reduce a large proportion of its grants to the level of commercial advertisement If it be alleged that the object of the above measure was to harmonise the law and practice of patents, it must be pointed out that the framers of this Act introduced at the last moment a clause to "round off" the official search by removing British patent specifications not retained on or included in the official files from the stock of public knowledge Thus the Common Law standard was sacrificed to official convenience. In this manner the English Law of Novelty has been made to box the compass. Valid patents can now be obtained without any consideration, for the disclosure may be identical with that already disclosed and published. The latter cannot be cited as evidence of prior anticipation. Let it be granted that no public inconvenience has arisen under the operation of this clause: but this admission undercuts the whole case for official examination so far as that examination is conducted through specifications of lapsed patents. The law obviously stands in need of a clear and business-like statement of its principles. An attempt in this direction was made in the Patents Act of 1919, which explicitly reaffirms the doctrine of the old Law as to "working", but as no concurrent relief was provided for the patentee on proof of commercial working, the value of the British patent continued on its downward path.

One step only remains to be taken to deprive our patent law of its last vestige of biological significance, namely, the abolition of protection to the importer of a new industry. This change, however, is foreshadowed in the Report of the British Empire Conference of 1922, the delegates to which suggest that this principle should be sacrificed on the altar of imperial uniformity

Is this country so far ahead of others in its industrial lead that it can afford to discard from its armoury the competitive principle which formed the basis of its early practice, securing for it that lead which it is frittering away to-day? The period of industrial progress, which dates from 1770, was marked by a continuous and fairly parallel growth in population and patent statistics which culminated in the year 1910 In 1911-12-13 the patent statistics began to fall away, and in the same year, 1911, the rate of growth of population showed a flattening tendency which has persisted to this day. These unfavourable symptoms are not equally reflected in the corresponding statistics of other countries

Hence a case appears to be established for an inquiry into the working of a system which, as the result of successive modifications during the last fifty years, has lost all claim to industrial value, consistency, or administrative economy In this inquiry all considerations of international or imperial comity should be subordinated to the national interest. The services of the inventor should be competed for by offering him the widest security for his monopoly compatible with the state of the national industry. On proof of commercial working, the validity of his patent should be freed from attack by proof of prior publication within the realm, and the patent freed from the payment of further renewal fees On these lines the law and practice could be made consistent, effective, and economical The cost of administration would be materially reduced, delays would be avoided, and a broad claim to the invention made secure so soon as the full consideration of the patent was given by its reduction to practice There would, no doubt, be some increase in litigation, but patent litigation is a sign of healthy progress These are matters clearly within the control of human agency, but courage and conviction are needed to bring about the reforms When a vacancy occurs in a university readership the stipend is fixed at a figure calculated, as Lord Bacon says, "to whistle for the ablest men out of all foreign parts." Educationists do not accept the latest thesis as a substitute for personal service. In the same way, new teachers in industry should be requisitioned to keep our manufactures abreast of foreign enterprise A nation which aspires to maintain its place in the hierarchy of power must conform to the teaching of natural laws.

Transcription of Russian Names.

I do not wish to prolong the correspondence upon this subject further than to say that in their letter appearing in NATURE, October 14, p. 512, Messrs Druce and Glazunov meet (in my opinion) none of the objections to a Czech-script transliteration of Russian pointed out in my letter (NATURE, July 15, p. 78), but merely reiterate their views,—in which, by the way, I think I could pick a number of holes were space available.

But I should prefer not being misquoted

I did not "ask how many English people can correctly pronounce Czech letters like *č*" (for, of course, any one can pronounce that letter, *i.e.* English *ch*). I said I wondered "how many Britons would pronounce this 'c' [that is, *ts*] correctly"—if they came across it suddenly in a Czech-script transliteration of Russian The same criticism applies to the quoted Russian х (= Czech *ch*), which would, therefore, be wrongly pronounced by the ordinary Briton as *ch* in church instead of as *ch* in loch

As I previously pointed out, the very simple Royal Geographical Society II system already exists in English; so why not use it? EDWARD GLEICHEN

Royal Geographical Society, Kensington Gore, London, S W 7, October 20.

APART from the typographical objections to a Czech transcription of Russian, which have been pointed out by Lord Edward Gleichen, there are other difficulties in its use From Prof. Brauner's examples his does not appear to be a uniform letter-for-letter system, at all events in the treatment of Russian "soft" vowels For example, the letter я, when initial, would presumably be transcribed *ja*, as in языкъ, *jazyk*; but if it happens to follow д, н or т, the letter *j* is dropped in the transcription and the Czech letters *ď*, *ň*, *ť*, are employed, *vide* Prof Brauner's examples *Taťana*, *Daďa*. And how is Russian "soft" р, which is represented in the Czech language by *ř*, pronounced *rzh* (*r* + French *j*), to be transcribed? For example, is рядъ to be rendered *řád*, which gives the wrong pronunciation, or *rjad*, which is not Czech?

Again, it is not clear how Russian е and ѣ are to be treated The natural Czech transcription would be *e* and *ě* respectively, but Prof Brauner writes *Mendělějev*, in which there are three different ways of transcribing Russian е.

The semivowel й is apparently to be transcribed *j*, but *ij*, *yj*, are not the Czech equivalents of ий, ый Does Prof. Brauner write *Čajkovskij*? (Incidentally, the average Briton would pronounce *čaj* like *cadge*)

Prof Brauner would, I hope, go so far as to abandon Czech for the transcription of Russian г, and would let us write *Vinogradov*, though the true Czech would be *Vinohradov*

Messrs Druce and Glazunov maintain (NATURE, October 14, p 512) that the system has the advantage of being complete; but what is the complete system? The foregoing points want clearing up

JOHN H REYNOLDS

Royal Geographical Society, Kensington Gore, London, S W. 7, October 21

Volcanic Shower in the N. Atlantic.

THROUGH the courtesy of Dr. Russell (Director) and of Mr. J. W. Carruthers, of the Fisheries Laboratory of the Ministry of Agriculture and Fisheries at Lowestoft, I am enabled to record a shower of volcanic dust that occurred near the Faroes on Thursday, October 5, soon after 5 A.M.

The captain of the steam trawler *Prince Palatine* reports that his mate directed his attention to what looked like a sudden appearance of land on the port quarter, when the vessel was about 62° 7′ N. and 7° 43′ W., Myggenæs (an islet west of Vagö) being on the starboard quarter A heavy sandstorm soon enveloped the vessel, lasting for the extraordinary period of sixty-seven hours, during which the air resembled that of a London fog, while the vessel was covered with a deposit from stem to stern Only a very small sample of the material is available; but Mr Carruthers rightly concluded that it consisted of volcanic glass With him, I note a few opaque particles, but these are in part white by reflected light, while others are merely fragments of deeply coloured glass. The material is a characteristic dust of volcanic glass, distinctly brown, and probably andesitic or basaltic I can trace no crystals, some of the particles show twisted wisp-like forms, and the majority are comminuted pumice, resulting from attrition in the air of masses in which the volume of vesicles exceeded that of glass. Branching forms, like spicules of lithistid sponges, are thus common. Mr Carruthers informs me that the Meteorological Office record shows that the position of the fall lay in a cyclonic depression, with a wind from somewhat east of south, blowing at 17 miles an hour

The duration of the fall may possibly be due to a circling round of some of the material Its occurrence seems worth recording, for comparison with dust that may have fallen on other ships at the same date. Some account may be forthcoming from the northern isles of the Faroe group It is most probable that the source was an eruption in Iceland, the dust having in that case travelled about 500 miles. The fine glassy dust has no doubt become sifted out from coarser matter during transit

GRENVILLE A. J. COLE.

Carrickmines, Co Dublin, October 21.

Orientation of Molecules in a Magnetic Field.

ABOUT this time last year, at the suggestion of Prof A W. Stewart, I began some work to test whether or not the molecules of a substance (more particularly at first of a liquid) underwent an orientation when placed in a magnetic field. So far the results all seem to indicate that something of the kind does take place The method first adopted was analogous to Laue's method of diffracting X-rays. A parallel pencil of X-rays was directed through a small cell containing barium iodide placed between the poles of a large electro-magnet, and was then received on a photographic plate During the first complete exposure no current was run through, during the next current was run through, and the process was repeated with a second pair of plates. In the case of both pairs of plates it was found that the disc which came up dark on development was greater in diameter for the exposure during which the magnet had been excited than for that when it had not been excited The increase was more than ten per cent. of the original diameter This effect may be analogous to that observed when a pencil of X-rays is passed through a powdered crystal. So far this method has not been used in a very refined manner, but it is hoped to continue with it and to improve it. The results obtained by it, however, have been corroborated by entirely independent methods, in which the properties of X rays were not made use of.

The question of the nature of the orientation, in addition to that of its occurrence, is still under investigation here, and I hope to be able shortly to make a further communication on this subject, giving more detail as to both the results obtained and the methods employed MARSHALL HOLMES.

The Sir Donald Currie Laboratories, Queen's University, Belfast, October 10.

The Ramsay Memorial in Westminster Abbey.

IT is a somewhat inhuman trait among British men of science, and in particular among chemists, that they have not sufficiently secured public honour for their fathers who spiritually begat them. Boyle's resting-place is unknown, and there is no express memorial to him in the Royal Society, of which he was the greatest founder; and to the chief of his chemical successors, however well remembered in the records of their science, tangible monuments for the most part exist only where purely local pride has preserved or erected them. The ceremony of November 3, therefore, when a medallion tablet in memory of Sir William Ramsay was unveiled in Westminster Abbey, was a most welcome manifestation of a world-wide tribute.

The British nation at large was represented in the person of H.R.H. the Duke of York (the Prince of Wales being prevented by a riding mishap), Sir Charles Sherrington, president of the Royal Society, stood for British science, together with a large gathering which included many of its foremost followers, Prof. Le Chatelier came from Paris as president of the Academy of Sciences; while the presence of the ambassadors and ministers of no fewer than twenty-one countries attested the far-reaching fame of Ramsay's achievements. Lady Ramsay was present, with Mr. W. G. Ramsay, and Dr. and Mrs. H. L. Tidy and their children. A short choral service was held in the nave, during which the Duke of York unveiled the tablet and offered it to the Dean, who in dedicating it referred to the panels commemorative of Joule, Kelvin, Hooker, Darwin, and Lister, among which it is to be permanently set. The medallion was provided from the Ramsay Memorial Fund.

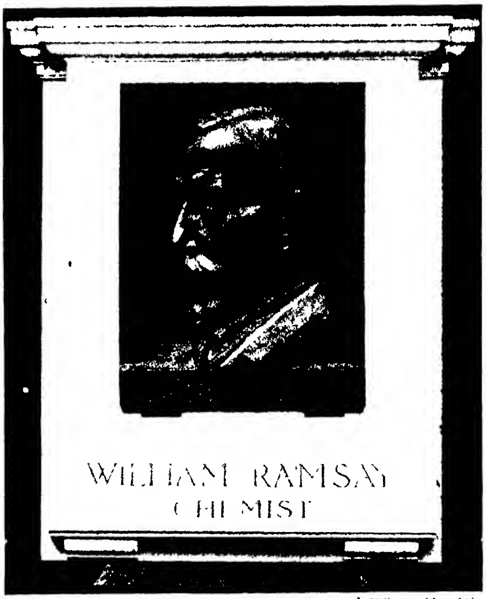

Photo.] [Elliott and Fry Ltd.
FIG. 1. The Ramsay Memorial, Westminster Abbey.

This fund, begun in 1917, consists of nearly 58,000*l.* raised by private subscription all over the world; and the capitalised value of the additional endowments by Dominion and foreign governments is as much again. Eleven Ramsay Fellowships, each of annual value at least 300*l.*, enable promising research-students to come to carry on work in any selected chemical laboratory in Britain, from Canada, France, Switzerland, Greece, Italy, Norway, Sweden, Denmark, Spain, Holland, and Japan, and there are also British Ramsay Fellowships, including one specially connected with Glasgow, Ramsay's *alma mater*. From the remainder of the fund, 25,000*l.* is being devoted to a laboratory of chemical engineering at University College, London, where Ramsay taught and worked for 26 years; there, also, an annual Ramsay medal has been founded.

The Abbey bronze, which was executed by Mr. C. L. Hartwell, A.R.A., is illustrated in the accompanying photograph (Fig. 1). The artist has been compelled, owing to the nature of the only position available in the Abbey, to give to the eyes a downcast expression which in life they rarely assumed. Probably no medium could convey the inward and outward sparkle which lit Ramsay's eyes under their characteristically lifted brows; and his open glance and the quick charm of his smile defy portrayal.

As a chemist, Ramsay had three great gifts in nearly equal degree: boldness of imagination, amazing audacity in conceiving experiments, and extraordinary constructional and manipulative deftness in carrying them out. Of his earlier researches the importance is exemplified by his discovery of the nature of Brownian movement, by the work embodied in the Ramsay-Young equation, and by that which gave the Ramsay-Eotvos method for measuring molecular association in liquids. In 1894, he alone of chemists had the courage to see in Rayleigh's abnormal nitrogen-densities the indication of a new atmospheric element and to seek it and find it, his discovery of helium came as a dramatic reward for a search after further sources of argon; and with the advent of liquid air he, with Travers, drove on with irresistible impetus to the detection and isolation of neon, krypton, and xenon. Only Berzelius has discovered as many new elements, no one but Ramsay has laid bare a complete and unforeseen group. In radioactivity he found fresh scope; and the experimental proof that helium is generated during radioactive change founded the era of the transmutation of elements. Possibly the finest example of his skill was given when, with Whytlaw-Gray, he measured the density of one-thousandth of a milligram of gaseous radium-emanation—the last member of his own group of inert gases.

Like Priestley and Davy, Ramsay opened up a new world for science; and physics, chemistry, and even astronomy are enriched, not alone by the discoveries which he made, but also by the methods which he devised and so freely handed on to others. I. M.

S. P. Langley's Pioneer Work in Aviation.[1]

By Prof. L. BAIRSTOW, C.B.E., F.R.S.

THE work of Prof. S. P. Langley in aviation is such a first-rate example of systematic inquiry—of a type rightly called scientific that no excuse is needed in again directing attention to it. Progress was made step-by-step in the face of formidable difficulties, and no attempts were made to solve the problems of mechanical flight by bursts of brilliance or invention. The scientific method appears to be most suitable for the great bulk of human endeavour and is required in the interpretation and development of striking innovations.

Langley was a creative investigator and not merely a producer of data. It is probably not wide of the mark to say that his experimental results are now rarely appealed to, yet who can doubt that the whole course of aviation was largely determined by his efforts? Langley's work may be divided into two periods—1887 to 1896, and 1896 to 1903. The end of this period is almost coincident with the earliest successes of the Wright Brothers. The later Hammondsport trials on a modified Langley aeroplane have obscured the real issue, and it is better to leave these out of account as having nothing to do with Langley and his methods.

The story can be readily told in extracts from the originals; in 1901 Langley said:

"And now, it may be asked, what has been done? This has been done: a 'flying machine,' so long a type for ridicule, has really flown, it has demonstrated its practicability in the only satisfactory way—by actually flying—and by doing this again and again under conditions which leave no doubt.

"There is no room here to enter on the consideration of the construction of larger machines, or to offer the reasons for believing that they may be built to remain for days in the air, or to travel at speeds higher than any with which we are familiar. Neither is there room to enter on a consideration of their commercial value, or those applications which will probably first come in the arts of war rather than those of peace, but we may at least see that these may be such as to change the whole conditions of warfare, when each of two opposing hosts will have its every movement known to the other, when no lines of fortification will keep out the foe, and when the difficulties of defending a country against an attacking enemy in the air will be such that we may hope that this will hasten rather than retard the coming of the day when war shall cease."

This note was written before the advent of the man-carrying aeroplane—two years before. Some of the prediction is yet unfulfilled, particularly that as to remaining for days in the air, but it accurately anticipated war uses before civil. In continuing his story Langley shows that he had no commercial interests in his efforts:

"I have thus far had only a purely scientific interest in the results of these labours. Perhaps if it could have been foreseen at the outset how much labor there was to be, how much of life would be given to it and how much care, I might have hesitated to enter upon it at all. And now reward must be looked for, if reward there be, in the knowledge that I have done the best in a difficult task, with results which it may be hoped will be useful to others. I have brought to a close the portion of the work which seemed to be specially mine—the demonstration of the practicability of mechanical flight—and for the next stage, which is the commercial and practical development of the idea, it is probable that the world may look to others. The world, indeed, will be supine if it do not realise that a new possibility has come to it, and that the great universal highway overhead is now soon to be opened."

This passage is of extreme interest; it emphasises the scientific spirit and the relation of science to industry. Monetary reward did not come to Langley, nor did the merits of his work save him from biting criticism in the press on the failure of his man-carrying aeroplane. Time has probably enabled us to take a more detached and fairer view. These early remarks by Langley prepare us for a note by his assistant, Mr. Manly:

"In the spring of 1904 after the repairs to the main frame were well under way, the writer [Mr Manly] on his own initiative undertook to see what could be done towards securing for Mr Langley's disposal the small financial assistance necessary to continue the work, but he found that while a number of men of means were willing to assist in the development of the aerodrome [aeroplane] provided arrangements were made for later commercialisation, yet none were ready to render assistance from a desire to assist in the prosecution of scientific work." On the other hand, Langley "had given his time and his best labours to the world without remuneration, and he could not bring himself at his stage of life to consent to capitalise his scientific work."

The problem of financing and directing scientific research is seen here as a striking example of the failure of our systems. The troubles still exist in large measure, and much has yet to be learnt before science and industry combine for efficiency and economy. The relation caused comment by Manly to the effect that:

"Persons who care only for the accomplished fact may be inclined to underrate the interest and value of this record [1911]. But even they may be reminded that but for such patient and unremitting devotion as is here enregistered, the new accomplished fact of mechanical flight would still remain the wild unrealised dream which it was for so many centuries."

Throughout his writings, Langley made a clear distinction between two subjects which he called "aerodynamics" and "aerodromics"—a distinction which still exists but is differently described. His division corresponds very closely with the modern expressions "performance" and "control and stability," both being now regarded as branches of aerodynamics. The scientific advisers of the Air Ministry are more and more turning to the study of "aerodromics," on which progress towards safety in flying is seen largely to depend. Its problems are still very difficult. In concluding this note probably the best summary is Langley's own:

"I am not prepared to say that the relations of power, area, weight, and speed, here experimentally established for planes of small area, will hold for indefinitely large ones; but from all the circumstances

[1] Extracted from an address delivered as chairman of the Royal Aeronautical Society on October 5.

of experiment, I can entertain no doubt that they do so hold far enough to afford assurance that we can transport (with fuel for a considerable journey and at speeds high enough to make us independent of ordinary winds) weights many times greater than that of a man" And

"I desire to add as a final caution, that I have not asserted that planes such as are here employed in experiment, or even that planes of any kind are the best forms to use in mechanical flight, and that I have also not asserted, without qualification, that mechanical flight is practically possible, since this involves questions as to the method of constructing the mechanism, of securing its safe ascent and descent, and also of securing the indispensable condition for the economic use of the power I have shown to be at our disposal—the condition, I mean, of our ability to guide it in the desired horizontal direction during transport,—questions which, in my opinion, are only to be answered by further experiment, and which belong to the inchoate art or science of aerodromics, on which I do not enter."

The problems of Langley are still problems, and we have very much to learn about the control of aeroplanes. An interesting commentary on Langley's work is provided by the fact that on October 19 the world's record for gliding flight was obtained on a replica of the Langley machine and not by a glider following the modern conventional aeroplane. It would be wrong, I think, to argue superiority of type for the successful glider, but it is a not unwelcome reminder of the enormous progress made by a scientific pioneer at a time when science in aviation is at a very low ebb.

The Early History of the Land Flora.[1]

By Dr. D. H. SCOTT, F.R.S.

II.

WHEN we reach the Upper Devonian flora we find ourselves in the midst of a comparatively familiar vegetation. A few of the early forms may have survived, but the bulk of the plants were highly organised Vascular Cryptogams or Spermophytes. While in the Early Devonian no true Ferns have been found, a branched, naked rachis being the nearest approach to a frond, the later vegetation has been called the Archæopteris flora, after the magnificent ferns or fern-like plants of that genus, of which the famous *A. hibernica* is the type We do not, however, know for certain whether these fine plants were really Ferns, or fern-like seed-plants. The presence of true Ferns is more surely attested by Dawson's Asteropteris, from the State of New York, which has the structure of a Zygopterid, a group well known from Carboniferous rocks. Lycopods had attained a very high development, as shown especially by the genus Bothrodendron, of which the large heterosporous cones are known.

The now extinct group of the Sphenophyllums, characteristic of Carboniferous times, had also made its appearance in the Upper Devonian flora; the whorled leaves of these early forms were deeply cut, not wedge-shaped as in most of the later representatives. Nathorst's genus Hyenia, which already appears in the Middle Devonian, may probably have been a precursor of the Sphenophylls

Another family, represented by Pseudobornia, of Nathorst, from Bear Island, is only known from the Upper Devonian It was a large plant, with whorled leaves, palmately divided, and further cut into narrow segments, while the long cones are believed to have produced spores of two kinds. Pseudobornia is at present quite isolated; its affinities may be either with the Sphenophylls or the Horsetails. Apart from this case, the Equisetales do not appear to be represented among our present Devonian records, for the evidence for the occurrence of Archæocalamites at that period seems to be inadequate. The group, however, was so well developed in Lower Carboniferous times that there can be no doubt it had appeared long before.

The best proof of the presence of seed-plants in the Upper Devonian is to be found in the occurrence of petrified stems, which, from their organisation, must presumably have belonged to advanced Gymnosperms. The genus Callixylon, apparently allied to the Lower Carboniferous Pitys, has a peculiar and beautiful structure in the secondary wood, the pits being localised in definite groups. The wood appears more highly differentiated than that of most living Conifers.

Thus the main lines of subsequent evolution were already well laid down in Upper Devonian times. We know practically nothing of their origin. Some botanists believe that the higher plants may have had a common source in some group, already vascular, such as the Psilophytales, while others hold that the main phyla have always been distinct, from the Algal stage onwards. The existence of these rival monophyletic and polyphyletic hypotheses, both maintained by able protagonists, shows how little definite knowledge of the evolutionary history we possess.

The Lower Carboniferous flora bears a close general resemblance to the Upper Devonian, but is much better known. The wealth of forms is, indeed, so great, that only the merest outline of the main features can be given here.

The Lycopods were abundantly developed. Many species of Lepidodendron and Lepidophloios are known, not only by external characters, but often by anatomical structure. While the primary ground plan of their anatomy was not unlike that of some of the simpler Lycopods of our own day, most of the old forms developed a considerable zone of secondary wood, and a massive periderm. They were, in fact, adapted to play the part of forest trees. The genus Sigillaria, however, so important in the Upper Carboniferous flora, was still scantily represented.

As regards their fructification, the Lower Carboniferous Lycopods had attained the highest level which the class ever reached. Not only were their cones constantly (so far as observed) heterosporous, with an extreme differentiation of the two kinds of spore, but some of them even developed a kind of seed, a structure quite unknown among Club-mosses of later than Carboniferous age. In the seed-like fructification

[1] Continued from p. 607.

(Lepidocarpon) a single megaspore only came to maturity, constituting the embryo-sac, while an integument, like a seed-coat, grew up round the sporangium.

The prothallus is sometimes well preserved, both in the seed-like bodies and in the more ordinary megaspores. In the latter (*Lepidostrobus Veltheimianus*), Dr. Gordon has recorded a perfectly typical archegonium, showing that the details of reproduction in these old Lycopods were the same as in their modern heterosporous representatives.

The best-known member of the Horsetail race was Archæocalamites, remarkable for the long leaves, often repeatedly forked, very different from the foliage which we are accustomed to associate with the Equisetales. The later Calamites were more or less intermediate in this respect. Anatomically, the Calamites, whether of Lower or Upper Carboniferous age, developed much secondary wood, and, like many contemporary Lycopods, became trees. The Lower Carboniferous Protocalamites is remarkable for possessing primary wood, centripetally formed, thus presenting some analogy with the Sphenophylls, in which this tissue is highly developed.

The cones attributed to Archæocalamites are, curiously enough, intermediate in structure between modern Equisetum cones and those of the Upper Carboniferous Calamites, for sterile bracts were either absent, or developed only at long intervals. In Equisetum, of course, they are absent altogether, while in the well-known Calamostachys and allied Upper Carboniferous fructifications, the sterile whorls are equal in number to the alternating fertile verticils It must be admitted, however, that our knowledge of Lower Carboniferous fructifications of this group is still somewhat scanty.

The Sphenophylls of the period were already very advanced, and in the genus Cheirostrobus appear to have reached their zenith. The great cones of this striking plant, with their elaborate and perfect apparatus of compound sporangium-bearing organs, and protective sterile appendages, are certainly the most complex cryptogamic fructifications known, from any period. Thus, in certain directions, the Lower Carboniferous plants had attained a height of development which has never since been equalled.

Sphenophyllum itself still had, for the most part, the deeply cut leaves of the Upper Devonian species. Where the anatomy is known (*S. insigne*, from Burntisland), it is of the same general type as in the later Upper Carboniferous forms, but apparently somewhat less specialised. It is worth remarking, that all the Sphenophyllums formed secondary wood, though they were small plants. Thus growth in thickness by cambium was not confined to arborescent forms in Palæozoic times, any more than it is now.

As regards the affinities of the Sphenophylls, some relation to the Horsetail stock seems evident, as indicated by the whorled leaves, the general organisation of the cones, and the detailed structure of the sporangia. Presumably these two lines sprang from a common source, but what it was is still unknown. Further affinities, once suggested, with the Lycopods and the recent Psilotaceæ have not been confirmed and are probably illusory. Neither has Lignier's hypothesis of a common origin of both branches of the Articulatæ from Ferns, gained any support from the fossil record. The Articulatæ, as a whole, remain a completely isolated phylum.

The Ferns of the Lower Carboniferous were well developed and varied. We meet with the usual difficulty in distinguishing between the fronds of true Ferns, and those of the so-called "Seed-Ferns," which simulated them in habit. Where, however, anatomical characters are available, we find no approximation whatever between the two groups. Pteridosperms and Ferns at all times show themselves perfectly distinct, whenever our knowledge admits of an adequate comparison.

We have fairly abundant structural material of Lower Carboniferous Ferns, but it seems that practically all of it represents the group called Primofilices by Arber, who by this name meant to suggest age, not primitiveness. They were curious plants, and many of them must have been very unlike any Ferns now living. Unfortunately, our knowledge of their habit is by no means equal to that of anatomical detail.

The chief family in the Lower Carboniferous is that of the Zygopterids, of which several genera are represented. As we have seen, this family had already appeared in Upper Devonian times. The vascular cylinder of the stem shows some differentiation of the wood into a central region (either a mixed pith or a core of small, short tracheids), and a wide outer zone of larger elements. The petiole always has a peculiar structure, with a bilateral strand (often of complex form) giving off branch-bundles to the right and left. It is remarkable that the genus Clepsydropsis, once thought primitive on account of its simple petiolar structure, has been shown to possess an exceptionally high organisation of the stem.

The most striking point is the morphology of the frond. Even where there were only two series of pinnæ (as in normal compound leaves) their plane was not parallel to that of the main rachis, but at right angles to it Moreover, in several genera there was the greater peculiarity that the pinnæ were in four rows, two rows on each side, a condition unexampled in ordinary leaves In Stauropteris this quadriseriate branching was repeated in successive ramifications, so that the form of the whole frond was compared by Lignier to a bush. In this genus it is practically certain that the leaflets had no blade, and throughout the family there is rarely any proof of its presence.

The other Lower Carboniferous family of Primofilices, the Botryopterideæ, is at present represented for that period by a single species, the *Botryopteris antiqua* of Kidston, a plant in all respects of simpler organisation than the Zygopterids, and apparently more like an ordinary Fern.

Sporangia are known in several cases. Those of Stauropteris were borne singly on ultimate branches of the frond; they had no annulus, and are very similar to the sporangia associated with the Early Devonian Asteroxylon. In the fructification attributed to Diplolabis the sporangia are grouped in a sort of synangium, while those associated with Botryopteris have a biseriate annulus.

Both families show some affinity with the older members of the Osmundaceæ, while a relation to the Adder's Tongues has also been traced. But in both directions the connexion seems to be somewhat remote.

We are dealing, in the Lower Carboniferous Primofilices, with early races, already specialised on their own lines, and probably only indirectly connected with the main current of Fern-evolution.

The "Seed-Ferns" or Pteridosperms appear to have attained a great development in Lower Carboniferous times. A considerable variety of seeds is met with, and in some cases there is strong evidence for attributing them to plants with a fern-like foliage. In one such example, described by Nathorst, the seed (Thysanotesta) is remarkable for having a distinct pappus; it was thus adapted to wind-dispersal, like the achenes of Composites.

No less than six families, referred to Pteridosperms, are known by their anatomy. In only one is there any evidence as to the seed, but all these groups show, in their structure, a nearer relation to known "Seed-Ferns" than to any other phylum. The case referred to is that of Heterangium, a genus with a solid wood and no pith. A beautifully organised seed (Sphærostoma, Benson), obviously related to that of the Upper Carboniferous Lyginopteris, is found in close association with *Heterangium Grievii* and probably belonged to it. The two genera, Heterangium and Lyginopteris, are closely related, as shown by Dr. Kubart's discovery of intermediate anatomical features, in species of Millstone Grit age.

The Lyginopterideæ extend to the Upper Carboniferous, but the other five anatomical groups are peculiar to the Lower.[1] They show a great variety in structure, but none of them bear any anatomical resemblance to contemporary Ferns. Our knowledge of so many, more or less isolated, types indicates that we have only found a few relics of what was really a most extensive class of plants.

The family most richly represented is that of which Calamopitys is the type. A number of species of Calamopitys are known; they are plants with a pith (sometimes "mixed"), large leaf-trace bundles, and much secondary wood. The petioles, often of large size and with many vascular strands, have long been known as Kalymma. Some of the species, with dense secondary wood of a Coniferous type, have been separated by Dr. Zalessky under the name Eristophyton. An interesting new genus, Bilignea, in which the pith is replaced by a central column of short tracheids, has been discovered by Dr. Kidston.

Apart from the "Seed-Ferns," we have the remarkable Lower Carboniferous family of the Pityeæ, already represented, as we have seen, in the Upper Devonian. Pitys was a genus of trees, with a relatively large pith traversed by slender strands of wood, while the secondary wood was of an Araucarian type. The foliage was quite unknown until recently, when Dr. Gordon discovered the leaves attached to the twigs in a species from the shores of the Firth of Forth. The leaves are totally different both from those of any Pteridosperm and from the well-known foliage of the Upper Carboniferous Cordaiteæ; they rather resemble the needles of a Fir, though more complex in structure. Dr. Gordon suspects an affinity with Araucarian Conifers.

Perhaps the chief conclusion that follows from this hasty sketch of the earlier floras is the great distinctness of the main phyla.

The Lycopods may perhaps become merged, as we trace them back, in the early Devonian Psilophytales, but nowhere approach any other group.

The Articulatæ appear as an isolated phylum throughout.

The Ferns may have come from thalloid plants, through some of the forms of Early Devonian age, where the frond is only represented by a bladeless rachis. The "Seed Ferns" now appear as a totally distinct line, parallel in certain respects to the true Ferns, but nowhere joining them, unless it be in some common thalloid source, about the Psilophytales level.

The higher Gymnosperms, represented in the period considered by Pitys and its allies, may have passed through an earlier Pteridosperm stage, but this is not proven. The Spermophyta generally may, for all we know, be as ancient as any other vascular plants.

Thus phylogeny still eludes us, though it remains the ultimate goal of the palæontologist.

[1] Space does not admit of any account of their remarkable characters. The five type genera are Rhetinangium, Stenomyelon, Protopitys, Cladoxylon and Calamopitys.

Obituary.

DR. C. G. KNOTT, F.R.S.

THE sudden death of Dr. C. G. Knott, reader in applied mathematics in the University of Edinburgh, and general secretary of the Royal Society of Edinburgh, has deprived physical science of a devoted follower and an accomplished exponent. On Wednesday, October 25, he was lecturing as usual and attending, in the afternoon, to the business of the Royal Society. At night he was taken ill and died of heart failure in a few hours.

Born at Penicuik in 1856, Knott entered the University of Edinburgh in 1872 and soon joined a little band of enthusiastic workers in the laboratory of Prof. Tait. To study under that great teacher was a privilege and an inspiration. The laboratory, then a new feature in university physics, was a small attic, meagrely equipped. Only a few of the best pupils cared to seek admission; they plunged at once into research, either sharing in the investigations on which Tait happened to be engaged, or undertaking some independent inquiry of their own. Tait was then collecting data for his thermoelectric diagram, and Knott's training was to measure the electromotive forces between pairs of some twenty different metals, through a wide range of junction temperatures. He also began the series of magnetic researches he was afterwards to pursue with the help of his own Japanese pupils. In 1879 he was appointed Tait's assistant, but gave up that post in 1883 when he became professor of physics in the University of Tokyo. After eight years as professor in Japan he returned, in 1891, to his own University of Edinburgh, where he spent the rest of his life, at first as lecturer and later as reader in applied mathematics. He also acted as the official adviser of students reading for honours in mathematics

and physics, or for degrees in science—a task which his wide knowledge, his unfailing good nature, his geniality, his ready sympathy, and his infinite capacity for taking pains, fitted him to discharge to the great advantage of many generations of undergraduates. For the last ten years he also held the office of general secretary in the Royal Society of Edinburgh, where the same characteristics found further exercise, along with others which eminently qualified him for editorial work.

In Japan, with pupils such as Nagaoka, Knott's influence as a teacher soon became conspicuous, and has proved enduring His love of research was infectious. The school of young Japanese seismologists and magneticians, then in its infancy, owed much to his example and encouragement. Along with Tanakadate, he carried out a magnetic survey of "all Japan" His industry was untiring and the habit of research, formed in his student days, never left him. All his scientific work is sound and thorough. His published papers, more than seventy in number, cover a wide range, but the subjects of ferro-magnetism, especially in its relation to strains, and of seismology, continued to engage his main attention. His book on the physics of earthquake phenomena, published in 1908, is an admirable digest of the whole subject, linking up the older with the newer seismology. His last long paper, published by the Royal Society of Edinburgh in 1919, completed a series in which the theory of earthquake-wave propagation is discussed with much originality

Probably the best known of Knott's books is his Biography of Tait (Camb. Univ. Press, 1911). No other disciple was so fit to undertake the difficult task of writing the life of the master, for on Knott the mantle had most directly fallen, and he, more than any, continued to wear it Tait himself, in a preface to his collected papers, speaks of Knott as an adept in quaternions as well as in physics, and adepts in quaternions have always been rare. Knott's grasp of mathematical methods, his intimacy with Tait's work and appreciation of Tait's genius, and above all his affectionate comprehension of an often whimsical personality, inspired him to write what is beyond question an exceptionally adequate and deeply interesting biography. More recently he organised the Napier tercentenary (1914), and edited the memorial volume. Almost his last act was to pass for the press the final sheets of collected papers by the late Dr John Aitken, F R S.

An unselfish, modest, Christian gentleman, whose life was a constant round of unobtrusive service, Knott is mourned by many friends J. A. E

By the death of Thomas Francis Moore the National Museum, Melbourne, has lost one of the most valued members of its staff Mr Moore had filled the position of osteologist at that institution for nearly twenty-two years His work was of a very high order and universally known As a link with the past, it may be mentioned that Mr. Moore's father, Mr. T J. Moore, was for forty years curator of the Liverpool Museum, and from 1865 to 1884 organised and took part in the Liverpool Free Public lectures Dr Frederick Moore, of the East India Company's Museum, well known by his work on oriental Lepidoptera, was an uncle of Mr. T. F. Moore

---

THE *Chemiker Zeitung* of October 17 reports the death, at the age of sixty-four years, of Prof. Lassar-Cohn, who had occupied the chair of chemistry at Konigsberg since 1894 His work was mainly in the fields of organic and technical chemistry, and his text-books were well known in English translations.

Current Topics and Events.

THE following is a list of those recommended by the president and council of the Royal Society for election to the council at the anniversary meeting on November 30 —*President* Sir Charles Sherrington, *Treasurer* Sir David Prain, *Secretaries* Mr W B Hardy and Dr J H Jeans, *Foreign Secretary* Sir Arthur Schuster, *Other members of Council* Prof V H Blackman, Prof. H C H Carpenter, Prof T R. Elliott, Prof A Harden, Sir Sidney Harmer, Prof W M Hicks, Prof H F Newall, Prof G H F Nuttall, Prof. D. Noel Paton, Lord Rayleigh, Prof O W Richardson, Sir Ernest Rutherford, Dr Alexander Scott, Mr F E Smith, Sir Aubrey Strahan, and Prof J T Wilson

It is announced in *Science* that Dr S W Stratton, director of the Bureau of Standards at Washington for the past twenty-one years, has been elected president of the Massachusetts Institute of Technology. Dr. Stratton was professor of physics and electrical engineering at the University of Illinois and professor of physics at the University of Chicago before his appointment as director of the Bureau of Standards in 1901, he found the department a small office employing three or four people, and from it he built up the present department with a staff of about 900. Commenting on Dr Stratton's resignation, Mr. Hoover is reported by the *New York Times* to have said "The Massachusetts Institute of Technology, an educational institution, finds no difficulty in paying a man of Dr Stratton's calibre three times the salary the government is able to pay him" It appears that it is impossible to live and to provide for old age while at Washington on a government salary, and for this reason it is difficult to induce men of science to undertake responsible national posts

PROF A SMITHELLS' retirement at the end of the present session from the chair of chemistry of the University of Leeds, after thirty-eight years of active work, will be a serious loss to the whole educational world as well as to the narrower sphere of academic life of the University in the progress and development of which he has played so conspicuous and devoted a part. His intention in retiring is to employ part

of his leisure in literary and scientific work with which his present multifarious duties, not only as head of a very large and busy department, but also as member of numerous university committees and outside public bodies, seriously interfere.

THE use of the cinema as a means of agricultural education among farmers is in contemplation in this country, and at least one organisation is understood to be preparing a set of films. A recent announcement in *Le Matin* indicates that France may, however, be first in the field. It is stated that the Ministry of Agriculture has submitted to the President of the Republic an order authorising an annual grant of 500,000 francs for the purpose of installing, in agricultural colleges and schools and in the rural communes, cinematographic appliances which would be used for the popularisation of scientific agriculture. There is no question that the cinematograph could serve a highly useful purpose; it is not only more attractive than the lantern slide, but it brings out points that could not otherwise be readily shown. It may be doubted whether the ordinary lantern slide could be dispensed with, however, and the lecturer of the future will probably try to use both films and slides.

AT the International Congress of Eugenics held in New York in 1921 an International Commission of Eugenics was re-formed from a previously existing committee. This committee held its first annual meeting at Brussels on October 7 and 9. By a unanimous vote it was decided to invite Germany to co-operate in its labours in the future, delegates from the United States, France, Denmark, Holland, Norway, together with Major Darwin, the chairman, and Dr. Govaerts of Belgium, the secretary, being present. The Société Belge d'Eugenique held a series of conferences at the same time, at which interesting papers were read. This society is to be congratulated on the assistance it is now receiving from the Solvay Institute, both as regards quarters and funds.

UPWARDS of eighty members and visitors attended the last conversazione of the Natural History Museum Staff Association for the current year, which was held in the Board Room on November 1. Among the many interesting exhibits placed round the room may be mentioned the following: A selection of birds collected in the course of the Shackleton-Rowett Expedition to the Antarctic regions by the *Quest*; life-size casts of the dolphins recently received by the Museum from Tung Ting Lake, China, about 800 miles from the sea; a series of specimens illustrating sporadic variation in plaice and flounder; life-size models in colour of toads and frogs shortly to be placed in the exhibition gallery; enlarged model of an extinct marine arthropod found in the Upper Silesian rocks of Oesel in the Baltic; examples of tropical spiders which have been discovered alive in this country; a selection of the butterflies collected in the course of the Mount Everest Expedition 1922, and a small fragment of the rock (biotite-schist) at the highest point reached by the climbing party; diagrams of genera of British Carboniferous corals, and others illustrating the distribution of mammals in Africa; and specimens illustrating the introduction of the chrysanthemum into this country in the eighteenth century. In addition, Mr. O. H. Little showed beaded casts of crustacean or worm tracks from the Nubian sandstone at Wady Arabah, Egypt. Messrs James Swift and Son exhibited recent models of their microscopes and accessories, and Messrs. Baird and Tatlock showed examples of glassware and other apparatus for museum and laboratory use.

THE Society of Chemical Industry, which was founded in 1881 for the promotion of applied chemistry and chemical engineering, has now a roll of some 5500 members scattered over all parts of the world. No less than eighteen local sections have been formed at home and abroad, each section having its own officers and programme, and leading to some extent an independent existence. There is also a chemical engineering group, which has its headquarters in London. The Edinburgh and East of Scotland section has included in its programme an address by Prof. G. Barger on some recent advances in biochemistry and another by Prof. H. S. Allen on modern theories of the structure of the atom, the latter being a joint meeting with the Glasgow section, the Royal Scottish Society of Arts, and the local section of the Institute of Chemistry. The programme of the Liverpool section is more industrial; papers have been arranged dealing with bleaching agents for textiles and paper pulp, chemical industry during the war in Great Britain and France, saponification of fatty oils, patent fuels, synthetic tannins, fractional distillation, and sulphur. These two programmes are wide and varied in their appeals, and serve to show the range of the society's activities.

THE report of the council of the North-East Coast Institution of Engineers and Shipbuilders for the year 1921–22, which has recently been issued, marks the close of the thirty-eighth session of the society. In addition to the presidential address by Sir William J. Noble, thirteen papers were presented at meetings during the session, and twelve are printed in the Transactions. They cover a wide field, there being three papers dealing with naval architecture, three with internal combustion engines, two with electrical and two with mechanical engineering, in addition to a paper on casualties at sea and another on standardisation. The roll of the society in July contained 1504 names, of which 486 were those of members, 542 of associate members, and 388 of graduates. The society benefited by two gifts of 500*l*. during the year; one was from Mr. A. E. Doxford, a past president, for the endowment fund, and the other from the Furness Shipbuilding Co., Ltd., to provide an income for the newly formed Middlesborough branch. The Graduate Section had a successful session, including, in addition to its formal meetings, a number of visits to works. Study circles inaugurated in 1920, specialising in the internal combustion engine and strength of ships, continued to meet. A

programme of the papers to be read and the works' inspections arranged for the Graduate Section during the current session has been issued and gives promise of an interesting and instructive series of meetings.

THE tenth annual meeting of the Indian Science Congress, under the auspices of the Asiatic Society of Bengal, will be held at Lucknow on January 8–13, 1923. The congress will be opened by Sir Spencer Harcourt Butler, Governor of the United Provinces, who has consented to be patron. The president of the congress is Sir M. Visvesvaraya, and the presidents of the sections are as follows: Agriculture—Dr. Kunjan Pillai, Trivandrum; Physics—Dr. S. K. Banerji, director of the Observatory, Colaba, Bombay; Chemistry—Dr. A. N. Meldrum, Royal Institute, Bombay; Botany—Mrs. Howard, Pusa; Zoology—Prof. G. Matthai, Government College, Lahore; Geology—Dr. Pascoe, Indian Museum, Calcutta; Medical Research—Lt.-Col. Sprawson, Lucknow; Anthropology—Dr. J. J. Modi, Bombay. In addition to the regular programme of the meetings of the scientific sections, a series of general scientific discussions has been organised, beginning with one on colloids by Dr. S. S. Bhatnagar, of Benares. A series of illustrated public lectures on subjects of popular scientific interest has also been arranged, details of which will be announced later. Further particulars regarding the congress may be obtained from Dr. C. V. Raman, general secretary, Indian Science Congress, 210 Bowbazaar Street, Calcutta. The local secretaries at Lucknow are Prof. P. S. MacMahon and Dr. Wali Muhammad of the Lucknow University.

THE British Non-ferrous Metals Research Association has just issued a statement as to the investigations already in hand and the work being undertaken by the Association. The record is one of active work, and is to be commended to other Research Associations as a model to be imitated. The practice has been to allot the investigations to existing laboratories of sufficient standing, the work being carried out under the direction of the chief of the laboratory in consultation with the Director of Research, Dr. R. S. Hutton. The subjects in which progress has already been made are: effect of small quantities of impurities on the properties of copper; conditions of obtaining sound ingots of brass; methods of jointing metals; abrasion and polishing of metals; atmospheric corrosion; properties of rolled nickel-silvers; influence of oxide on aluminium; and cause of red stains on finished brass. Information has also been collected respecting the electric melting of non-ferrous metals. In regard to the first of the subjects mentioned, the effect of oxygen on copper has been studied in detail and the effect of other elements is now being examined. The laboratories with which arrangements have been made include the National Physical Laboratory, the Universities of Birmingham, Sheffield, and Manchester, the Research Department, Woolwich; the Royal School of Mines, and the Research Department of Metropolitan Vickers, Ltd. The pamphlet also contains particulars of the means adopted for circulating information among members, and concludes with an outline of the future work proposed for the Association.

A STATE Institute of Radiology has been established at Prague, under the direction of Dr. Felix.

IN consequence of the great demand for seats at the joint meeting of the Royal Geographical Society and Alpine Club for the Mount Everest film lecture on November 21 at the Central Hall, London, it has been found necessary to arrange two meetings—for the afternoon at 3 P.M. and the evening at 8.30 P.M.

A PRIZE of 1000 guineas has been offered by Messrs. Selfridge and Co., through the Royal Aero Club, for the first flight of fifty miles made by a British pilot on a British-built glider, the distance to be measured in a straight line from a given point of departure. The prize will remain open for a year from January 1, and if it is not awarded, a prize of five hundred guineas will be given for the longest flight of more than twenty-five miles during the year.

IT is announced in *Science* that the Howard N. Potts Medal of the Franklin Institute has been awarded to Dr. Charles Raymond Downs and Mr. John Morris Weiss of New York "in consideration of their notable achievement in the scientific and commercial development of the catalytic vapour-phase oxidation of benzene to maleic acid and their pioneer work in developing a commercial process for changing aromatic to aliphatic compounds."

WE have referred in these columns from time to time to the preparations which are being made in France to celebrate the approaching centenary of the birth of Pasteur. British men of science have had an opportunity of sharing in the celebrations and we now learn from *Science* that the New York Academy of Medicine is organising an exhibition in commemoration of the event. The exhibition, which will be opened on December 27, will consist of a collection of books, manuscripts, photographs, engravings, etc., illustrating the life and work of Pasteur, and will conclude with a number of addresses by distinguished members of the medical profession.

A NEW Danish expedition to the Sahara is announced in the *Times*. Under the leadership of Prof. Olufsen, the expedition will shortly leave Tunis for the Shat-el-Jerid. From Netta it will go by Tuggurt to Wargla in the Algerian Sahara, and thence to Insalah, and endeavour to explore the Hoggar Mountains. The members of the expedition will include Dr. Gram, botanist, Drs. Storgaard and Kayser, geologists, and Prof. Bourcart, of the Sorbonne. Dr. Olufsen expects that the journey will occupy some six months.

NEWS from Mr. K. Rasmussen brings the story of his researches in Baffin Land and the Hudson Bay region down to the end of July. According to the *Times* the winter work was carried out according to programme. Surveys were made of the north coast of Fury and Hecla Straits, and that part of Baffin Land between Gifford Bay and Admiralty Inlet. Mr. Rasmussen himself was chiefly engaged in his

researches on the migration routes of the Eskimo, and in order to become acquainted with the local dialect stayed several months in a small Igdluhk settlement at Cape Elisabeth. At the end of March Mr. Rasmussen, with two companions, left for Chesterfield Inlet on his way to the Aivilik and Netjilik tribes. Baker Lake was reached early in May and Yathkied Lake in June. From there the party returned in July to Chesterfield Inlet. The country between Chesterfield Inlet and Yathkied Lake is inhabited mainly by pronounced inland tribes of Eskimo who only during recent decades have begun migration to the sea coast. They live on bad terms with the nearest Indian tribes, and some of them had never seen white men. Their legends often agree in minute detail with the Greenland legends; their religion is on a much lower level. Mr. Rasmussen considers these tribes to be the most primitive that he has ever met: this is also shown in weapons, houses, and boats. Everything connected with the sea is taboo. The stone houses are unheated, as no blubber is available. Salmon fishing and reindeer hunting are the only means of livelihood, and starvation is not an uncommon experience of these tribes. Steensby's theory that the Eskimo were originally inland American people receives support from these discoveries. The inland tribes which Mr. Rasmussen studied very likely may be the last survivals of the primeval Eskimo who have not yet reached the sea.

PROF. LEONARD HILL delivered a Chadwick Public Lecture on "Ventilation and Atmosphere in Factories and Workshops" on October 26. Prof. Hill emphasised the fact that it is not the relative humidity that matters, but the actual vapour pressure of the air coming in contact with the skin; the breathing of cool air entails more evaporation from the respiratory membrane and consequent greater outflow of lymph through the secretion of fluid from it. Thus the membrane is better washed and kept clean from infecting microbes. The open-air worker is thus better protected, and moreover escapes the massive infection from carriers which occurs in shut-up rooms. Wet-bulb temperatures in factories and mines are physiologically more important than dry-bulb temperatures; the velocity of the air is an important consideration, for on this chiefly depends cooling by convection and evaporation. The cooling and evaporating powers of an atmosphere can be measured by the kata-thermometer, a large-bulbed spirit thermometer. Furnace- and engine-rooms should be ventilated by fans at the bottom of wide trunks down which cool air naturally sinks, the fan breaking up the air into fine streams. Rooms are best ventilated by open windows or a system of fans to impel cool fresh air through gratings about eight feet from the ground and extract it through apertures in the ceiling; floors and walls should be warmed by radiant heat from gas or coke fires.

THE Eastman Kodak Company of New York has issued the fourth volume of "Abridged Scientific Publications from the Research Laboratory of the Eastman Kodak Company," a volume of about 340 pages. It includes abridgments of 54 papers that have been published during the years 1919 and 1920 in various scientific journals and the proceedings of scientific societies. The abridgments are not mere expansions of the titles, as is too often the case just now, but useful and often long abridgments giving details of methods and results. At the end of the volume there is a complete list of all communications issued by the Laboratory (a total of 117), and indexes of authors and subjects for the four volumes. The subjects dealt with cover a very wide range. Besides those that are obviously related to photography, which are divided into nine sections, there are papers on photometry, colour measurement, sensitometry, photographic optics, physiological optics, chemistry, physical chemistry, electro-chemistry, colloids, and radiography. The volume is undeniable evidence of the activity of those who work in this Laboratory and of the broad views taken of the subject by the Director.

WITH reference to Dr. Hale Carpenter's letter describing a waterspout published in our issue of September 23, p. 414, we have received a letter from Mr. E. R. Welsh, Devon, Pa., U.S.A., in which he suggests that in a waterspout, centrifugal force would cause a partial separation of air and waterdrops, the waterdrops tending to concentrate in an outer sheath, while within the sheath there would be a region with lower waterdrop content; the continued existence of the central core would be provided by the uprush of spray from the surface of the water. Mr. Welsh suggests that the appearance of pulsation in the outer sheath might be explained by the rotation, combined with a spiral fluting of the sheath.
